Fig. 1 Rearrangement of immunoglobulin genes and the generation of diversity in humans. (A) The human IGH locus is comprised of sets of IGHV, IGHD and IGHJ gene segments. A rearranged immunoglobulin gene is generated by genomic recombination events that first join single IGHD and IGHJ gene segments, followed by joining to a single IGHV gene segment. (B) Joining of gene segments is imprecise as hairpin structures that form following RAG cleavage at RSS sites are opened asymmetrically and the joints are acted on by exonucleases that remove nucleotides from coding ends and TdT which incorporates untemplated nucleotides, leading to diverse junctions. (C) The IGH and light chain polypeptide chains are joined by disulfide bonds (pink) to form an immunoglobulin protein which is broadly divided into variable and constant regions. (D) Rearranged immunoglobulin genes are associated with IGHC exons at the mRNA level, naïve B cells can express both IgM and IgD through alternative splicing. Genomic recombination events can alter the IGHC locus leading to expression of downstream isotypes classes and subclasses. (E) Rearranged genes undergo somatic hypermutation and class switch recombination as part of the B cell clonal expansion to give rise to B cell lineages.

'junctional' which generate the vastly diverse naïve B cell compartment (**Fig. 1(A)** and **(B)**). Naïve B cells are those that are yet to experience foreign antigen interactions. Diversification subsequent to antigen encounter is SHM driven.

Combinatorial Diversity

IGH are formed via the joining of three distinct gene segments; IGHV, IGHD and IGHJ. Sets of each type of gene segments are present within the IGH locus on chromosome 14. IGH gene segments are both polygenic and polymorphic. Within the human population each gene may exist as a number of allelic variants with any single individual carrying just one (homozygous) or two (heterozygous) of the possible alleles ([Watson et al., 2013](#)). More than two variants of some genes, for example IGHV1–69, may be carried by a single person due copy number variant haplotypes ([Watson et al., 2013](#)).

Functional IGH gene segments are flanked by recombination signal sequences (RSS) ([Tonegawa, 1983](#)). Each RSS is composed of a conserved heptamer (6 base pairs) and nonamer (9 base pair) sequence separated by a variable spacer region of either 12 ± 1 (IGHD segments) or 23 ± 1 (IGHV and IGHJ segments) base pairs (bp) in length. Only genes with different spacer lengths can efficiently recombine and this 12/23 rule promotes the preferential formation IGHD: IGHJ and IGHV: IGHDJ joins. The formation of the rearranged immunoglobulin variable gene that will eventually be transcribed as the IGH begins with the pairing of single IGHD and IGHJ segments from the approximately 25 IGHD and 6 IGHJ segments within an individuals' IGH locus. Subsequently, the IGHD: IGHJ will be joined to one of between 45 to 50 functional IGHV segments ([Boyd et al., 2010](#); [Kidd et al., 2012](#); [Watson et al., 2013](#)) to give the rearranged IGH variable region gene.

The recombination of select gene segments to generate the final gene sequence provides for approximately 22,500 unique IGH rearrangements as the IGHDs can be used in all three reading frames (RFs). The light chain provides for approximately 200 different IGKs by recombining 34 to 40 IGKV to 5 IGKJ and 165 lambda light chains combinations from joining between 29 to 33 IGLV and 5 IGLJ. The pairing of heavy and light chains therefore provides for just over 8 million unique antibodies.

A number of biases in the joining of particular segments to each other have been observed, for example, a tendency for 3' IGHD genes to preferentially pair with 5' IGHJ genes ([Kidd et al., 2016](#); [Volpe and Kepler, 2008](#); [Souto-Carneiro et al., 2005](#)). This may be the result of RSS efficiency or other mechanisms such as chromatin structure that impact gene segment accessibility.

Junctional Diversity

The approximately 8 million immunoglobulins formed from combinatorial diversity accounts for only a fraction of the predicted diversity of the immunoglobulin repertoire within a single individual's repertoire. Further diversity stems from the imprecise nature of the gene segment joining with nucleotides added and removed during the recombination process (**Fig. 1(B)**) ([Alt and Baltimore, 1982](#); [Lafaille et al., 1989](#)). Joining of two gene coding segments begins with the recruitment of the lymphocyte specific Recombination Activation Gene (RAG) complex consisting of RAG-1 and RAG-2 proteins to the RSS elements ([van Gent et al., 1995](#)). The RAG complex introduces a nick between the RSS and the adjacent gene coding segment that is converted a double-stranded break with the formation of a covalently sealed hairpin on the gene coding side of the break ([McBlane et al., 1995](#)).

The hairpin loops at the gene segment ends are opened by a complex formed between the nuclease Artemis and the catalytic subunit of the DNA-dependent kinase (DNA-PK_{CS}) ([Ma et al., 2002](#)). Artemis preferentially cleaves the hairpin loop at a position 3' to the tip generating a single stranded overhang (**Fig. 1(B)**). The single stranded overhang is an inverted repeat of the sequence of the end of the gene segment and this sequence may be incorporated into the rearranged gene as palindromic (P) nucleotides. The overhangs of the open hair pins are processed in two ways - exonuclease trimming and non-template encoded (N) addition ([Lafaille et al., 1989](#)). Exonuclease trimming may remove all P nucleotides, plus additional nucleotides from the coding sequence beyond the original break. The nuclease responsible is unknown. N nucleotide addition arises from the incorporation of free dNTPs to the 3' end of DNA by the short isoform of nuclear enzyme terminal deoxynucleotidyl transferase (TdT) within the joint ([Benedict et al., 2000](#)). These regions are termed the N-regions (N1 at the IGHV to IGHD join and N2 at the IGHD to IGHJ join). TdT preferentially incorporates G. Following processing, the joint between the two gene segment ends is resolved by non-homologous DNA end joining ([Lieber, 1999](#)).

Somatic Hypermutation

SHM expands the diversity of the immunoglobulin repertoire and tailors antibodies and BCRs for higher affinity interactions with antigen (**Fig. 1(E)**). SHM takes place within specialized micro-environments within secondary lymphoid tissue call germinal centers (GC) ([Bannard and Cyster, 2017](#)). Within the GC, B cells undergo rapid clonal expansion, during which the B cell's immunoglobulin genes mutate at the rate of approximately 10^{-3} changes per nucleotide per cell division. Point mutations are introduced into the domain that starts approximately 150 bp downstream from the IGHV promoter and extends 2kpbs downstream with a frequency that decays exponentially from the IGHV promoter ([Rada and Milstein, 2001](#)).

Substitutions are targeted to intrinsic mutational hotspots ([Jolly et al., 1996](#)). Activation induced cytosine deaminase (AID) is specifically expressed in activated B cells and undertakes targeted deamination of deoxycytidine residues ([Muramatsu et al., 2000](#)). Deamination of C by AID changes C:G base pairs to U:G mismatches and is targeted to WRC motifs with a major intrinsic hotspot being overlapping WRC motifs on the coding and non-coding strands – WGCW – which suggests that AID binds as an oligomer ([Ta et al., 2003](#)). The U:G mismatch can be resolved in a number of ways. Replication using the mismatching template can produce transition mutations where C/G are replaced by A/T. Alternatively, the U can be removed by uracil-DNA glycosylase such as UNG2 creating an apyrimidinic site (AP) which can be repaired by base excision repair (BER) ([Teng and Papavasiliou, 2007](#)). As BER

results in untemplated replication opposite the AP site any dNTP can be incorporated at the position leading to either reversion, transition or transversion mutations. The nucleotide inserted is dependent on the DNA polymerase involved in the BER as polymerases are biased in the nucleotides that they insert.

Targeting of mutations to A:T pairs may arise through several proposed mechanism (Teng and Papavasiliou, 2007). For example, the binding of MSH2-MSH6 at U:G mispairs can recruit exonuclease 1 where it can create a gap that when filled by an error prone polymerase leads to mutations at A:T pairs. Alternatively, during short patch repair of the AID U:G lesion, U may be inappropriately incorporated due to dNTP pool imbalances creating A:U mispairs in the region surrounding U:G lesion and the resolution of the A:U mispair may introduce mutations at A:T pairs.

Sequencing of Immunoglobulin Gene Repertoires

Each immunoglobulin transcript captures details of the gene segments that formed the rearranged gene, the processing the that gene segments underwent during recombination, and, if the B cell has encountered antigen, the mutations that have accumulated during affinity maturation, along with the isotype subclass that the VDJ is associated with. Amplicons from tens to hundreds of thousands of B cells may be sequenced from a single peripheral blood sample to capture the different members of clonal expansions. Furthermore, as VDJ rearrangement is an intra-chromosomal event, analysis of low mutation rearrangements can also inform on the underlying immune genotype and haplotype of the individual (Boyd *et al.*, 2010) (Kidd *et al.*, 2012). Repeated longitudinal sampling from a single subject over the course of an immune response, such as infection or vaccination, allows tracking of the origin and fate of B cell clones over the course of the response.

Several approaches for deep sequencing of immune receptor repertoires have been published (Jackson *et al.*, 2014; Galson *et al.*, 2015; Ellebedy *et al.*, 2016). The common themes to these protocols are amplification from cDNA to capture VDJ and isotype information and multiplexing of samples using nucleotide sequence barcodes to permit single libraries to be generated from many different samples. Some protocols incorporate unique molecular identifiers (UMI) at the cDNA synthesis step to tag each RNA molecule with unique identifier before PCR amplification to allow counting of single transcripts and for error correction (Turchaninova *et al.*, 2016). In addition to cDNA based protocols, the relationship between single B cells and amplicons may be maintained by genomic DNA amplification in replicate to study clonal expansions at the sacrifice of isotype information (Boyd *et al.*, 2009).

Full length VDJ amplified from leader primers, or near-full length from FR1 primers, with enough CH1 exon to discriminate IgG and IgA subclasses can be captured using paired end libraries sequences on the Illumina MiSeq platform with 600 cycle kits for in excess of 20 million reads. Longer read, lower throughput technologies, such as PacBio and Oxford Nanopore have potential to offer ability to capture full length VDJ plus constant region amplicons. Usually amplifications are from bulk cell populations, either total peripheral blood mononuclear cells or sorted cell populations from fluorescent or magnetic cell sorting to enrich to particular phenotypic cell subsets (eg. plasmablasts, memory B cells, activated B cells, or naïve B cells), however, immunoglobulin genes may also be studied from single B cells, to capture paired heavy and light chain gene transcripts (Busse *et al.*, 2014). Attempts have also been made to reconstruct rearranged immunoglobulin genes from single cell RNA transcriptome sequencing methods to permit linking of paired heavy and light chain transcripts to overall gene transcription within a cell (Rizzetto *et al.*, 2017).

Analysis of Immunoglobulin Gene Sequences

Partitioning of Rearranged Immunoglobulin Genes

The most basic challenge of the study of immune receptor genes through sequencing datasets is the partitioning of rearranged genes into their various components such as IGHV, IGHD and IGHJ segments and identification of nucleotide loss and addition of the IGHV-IGHD and IGHD-IGHJ joints to determine of SHM spectra.

A number of tools exist for this purpose (Table 1). The earliest contributions to the field treated the partitioning problem as three separate alignment problems; one for each gene segment. These include IMGT/V-QUEST (Brochet *et al.*, 2008), which appears to be based on a dynamic programming algorithm with a single recursive rule as alignment scores are re-created by a simple derivation of the Smith-Waterman local sequence alignment algorithm, and IgBLAST (Ye *et al.*, 2013) based on the Basic Local Alignment Search Tool (BLAST) algorithm (Camacho *et al.*, 2009). Contemporary tools have attempted to gain speed advantages to the alignment-approach by using modified kmer-chaining based methods (MiXCR (Bolotin *et al.*, 2015)), dynamic programming algorithms constrained by conserved motifs (HTJoinSolver (Russ *et al.*, 2015)) and fast-tag-searching algorithms (LymAnalyzer (Yu *et al.*, 2016)). IMGT/V-QUEST and IgBLAST remain perhaps the most widely used germline gene annotation tools for rearranged gene sequences. Only MiXCR identifies the associated isotype from the IGHC gene, otherwise this is undertaken a customized post-processing step using BLAST (Camacho *et al.*, 2009) or string matching.

The variety of processes that underlie the gene rearrangement however complicate the partitioning, particularly the discrimination of the components within the CDR3 that spans from the IGHV end, across the V-D junction, IGHD, D-J junction, through to the IGHJ start. Tools specific for the CDR3 were therefore developed. The first wave of such tools included IMGT/Junction Analysis (IMGT/JA (Yousfi Monod *et al.*, 2004)) and JOINSOLVER (Souto-Carneiro *et al.*, 2004). IMGT/JA uses a five-stage process to identify the P nucleotides, the N nucleotides, the IGHD, to consider the processing of IGHV and IGHJ ends, and to

Note: The 'type' column provides a general classification for the tool; 'analysis' tools focus on performing targeted analysis on processed datasets; 'annotation' tools focus on the partitioning of rearranged sequences into their components; 'germline inference' tools attempt to define the genotypes from rearranged datasets; 'GUIs' provide easy-to-use interfaces for tools or pipelines; 'pipelines' are end-to-end solutions starting from raw data; 'post-analysis' tools offer general post-processing of annotated datasets, and 'single-cell' are tools for the reconstruction of genes from single cell datasets.

allow for somatic point mutations within the ends by placing predefined maximum values on the number of mutations and by excluding the possibility of consecutive mutations (Yousfi Monod *et al.*, 2004)).

The location of the IGHD amongst the N-additions means that care must be taken to delineate N additions from germline gene contributions. JOINSOLVER considers the likelihood that N-addition may give rise to sequences that mimic germline IGHDs (Souto-Carneiro *et al.*, 2004) by defining the maximum number of consecutive matches that differentiate between a true germline IGHD gene and N-additions. The minimum number consecutive matches were determined using a Monte Carlo simulation whereby large simulated datasets representative of N additions are used to calculate the frequency at which IGHD sequence motifs occur to establish probabilities. For appropriate probabilities to be calculated the simulated N additions should reflect real N-additions and models for simulation of N additions have been proposed (Jackson *et al.*, 2007).

Partitioning approaches also consider the problem of immunoglobulin partitioning in the context of the biological rearrangement process. Rather than a series of local alignments against reference sets of germline genes, models of rearrangement are created, and mathematical techniques are used to find the combination of germline genes, mutation and nucleotide loss and addition that best explain a rearranged sequence in the context of the model. SoDA for example utilized a 3D alignment algorithm for simultaneous alignments of all genes segments and to account for nucleotide loss and addition (Volpe *et al.*, 2006). JointML uses a maximum likelihood method to determine the best fit to a model of IGH rearrangement that considers all possible combinations of germline genes and N and P additions (Ohm-Laursen *et al.*, 2006), and iHMMune-align uses the veterbi algorithm to find the best path through a hidden markov model (HMM) which consists of a series of probabilistically defined states whose relationship to each other are described by transitions that are themselves also associated with probabilities (Gaeta *et al.*, 2007). These utilities were developed in the pre-deep sequencing era and generally do not scale well to very large repertoire datasets.

Contemporary tools that use model-based approaches include partis (Ralph and Matsen, 2016a), IGoR (Marcou *et al.*, 2017) and IgSCUEAL (Frost *et al.*, 2015). The partis package uses a novel HMM factorization strategy across large datasets to build a parameter rich model for partitioning of individual sequences into their germline gene and N addition contributions. It overcomes the limitations of previous HMM-based approaches by using flexible categorical distributions rather than probability distributions, implementing a new HMM compiler (ham), and by performing inferences on collections of HMMs rather than a single all-encompassing HMM (Ralph and Matsen, 2016a). IgSCUEAL attempts to annotate IGHV and IGHJ genes within rearrangements using a phylogenetic-based approach that combines a genetic algorithm with maximum likelihood fitting of evolutionary models, but IGHD identification is performed using pair-wise alignment (Frost *et al.*, 2015). IGoR uses a Sparse Expectation-Maximization algorithm to learn statistics of rearrangements for use in annotating rearranged genes in a probabilistic manner and can also generate simulated repertoire datasets based on the learned statistics (Marcou *et al.*, 2017).

Gene Reference Datasets and Allelic Inference

The major reference set utilized in the analysis of rearranged immunoglobulin genes is the IMGT reference set (Lefranc and Lefranc, 2001). Alternative collections of human immunoglobulin gene segments include NCBI (Ye *et al.*, 2013) and VBASE2 (Retter *et al.*, 2005). As increasingly diverse human populations are studied it has become apparent that existing reference datasets do not capture all polymorphisms that exist in the human population (Watson *et al.*, 2013; Boyd *et al.*, 2010; Kidd *et al.*, 2012; Watson *et al.*, 2015; Wang *et al.*, 2011; Scheepers *et al.*, 2015).

Several tools for the inference of novel gene segment polymorphisms within repertoire datasets have been developed including IgDiscover (Corcoran *et al.*, 2016), TIGGER (Gadala-Maria *et al.*, 2015), LymAnalyzer (Yu *et al.*, 2016) and IMPre (Zhang *et al.*, 2016). These tools leverage the ability of rearranged immunoglobulin genes to be used to infer set of available gene segments within the IGH locus of an individual (Boyd *et al.*, 2010). IgDiscover applies an iterative clustering, consensus building and filtering algorithm to IgM antibody libraries to define dataset specific germline gene segment sets *de novo* (Corcoran *et al.*, 2016). TIGGER utilizes datasets that have previously been aligned against a reference set, such as the IMGT reference set (Lefranc and Lefranc, 2001), and applies regression-based methods to detect distinct patterns of SHM to distinguish polymorphic positions from positions targeted by SHM (Gadala-Maria *et al.*, 2015). LymAnalyzer is a toolkit that aligns to the IMGT reference set using a fast-tag-search alignment and applies a two-step heuristic approach, adapted from (Boyd *et al.*, 2010), to the detection of novel alleles in the aligned data, testing for enrichment of a mismatch to the reference in multiple distinct rearrangements and requiring the difference to be present in at least 10% of the alignments to a reference gene (Yu *et al.*, 2016). IMPre utilizes a custom algorithm combining k-mer seed clustering, multiway tree-based assembly and optimization by filtering, merging and error correction, for *de novo* inference of germline gene segments from rearranged repertoire datasets (Zhang *et al.*, 2016).

Analysis suggests that parallel use haplotype inference, as originally proposed by (Kidd *et al.*, 2012), in conjunction with novel allele inference, provides for high sensitivity and specificity in repertoire analysis (Kirik *et al.*, 2017). The use of dataset specific reference sets does however restrict the options with respect to partitioning tools to those, such as IgBLAST (Ye *et al.*, 2013), that permit the user defined datasets, or to the application of re-assignment methods such as within TIGGER (Gadala-Maria *et al.*, 2015). Attempts to define additional allelic variants using other data sources have also been undertaken. For example, AlleleMiner (Yu *et al.*, 2017) attempts to recover immunoglobulin gene segments alleles from genomic sequence data by mining genomic variant calls from the short-read sequencing datasets such as the 1000 Genomes Project data. There are many challenges in building reference datasets from this type of single nucleotide polymorphism (SNP) data and caution must be exercised especially with respect to the mapping of the SNP data to the reference prior to inference (Watson *et al.*, 2017).

Analysis of Clonal Lineages

Once a dataset of high quality annotated gene rearrangements has been gathered it is desirable to understand the lineage structure within the dataset, or across datasets in the case of longitudinal or multiple subset or multiple site sampling from a single subject. Historically, this has been approached as a sequence clustering problem aimed at grouping highly similar immunoglobulin gene rearrangements together under the assumption that their similarity has resulted from their sharing the same initial B cell. This often involves clustering the CDR3 sequences of rearranged IGH that share the same IGHV and IGHJ segments and have equal CDR3 lengths at an identity threshold that allows for some SHM within the CDR3 but which shouldn't bring together CDR3s that were generated by distinct VDJ recombination events.

Several software packages implement sequence-based clustering for clone grouping, for example, IMSEQ's clone building using shared CDR3 sequences (Kuchenbecker *et al.*, 2015) and the clone clustering within the ImmuneDB (Rosenfeld *et al.*, 2017). The clone clustering implemented by ImmuneDB, which iterates over unique reads in descending size order, grouping smaller copy reads with higher count reads where they differ by less than 15% at the CDR3 amino acid level, was recently applied to B cells sampled from a number of different anatomical sites to develop an atlas of B-cell clonal distribution (Meng *et al.*, 2017). An attempt to improve on the results of sequence-based clustering approached is offered by the likelihood-based clonal inference using multi-HMMs implemented as part of partis (Ralph and Matsen, 2016b).

Detection of Antigen Selection

Antigen selection refers to testing whether or not the mutational spectra of immunoglobulin genes have been influenced by enrichment of mutations predicted to improve interaction with antigen. One package for testing if mutational distributions have been skewed by antigen selection is BASELINE (Yaari *et al.*, 2012). BASELINE provides a framework for quantifying the strength of antigen selection on individual sequences or within clonal lineages using Bayesian estimates of replacement frequency and has the capacity to aggregate probability density functions over multiple sequences in order to compare sets of sequences.

Additional approaches for studying antigen selection have been described, but not implemented as tools. Approaches are largely based on detecting an enrichment of mutations that have led to amino acid substitutions within the CDRs, and the avoidance of such changes in the FRs, and differ in their hypothesis testing statistics. The first of such methods was proposed by (Shlomchik *et al.*, 1987) and tested replacement (amino acid change) and silent (no amino acid change) in CDRs and FRs against a random model of mutation using the binomial distribution. This was later modified by (Chang and Casali, 1994) in an attempt to better account for the differences in codon usage between CDRs and FRs as CDRs are more intrinsically biased toward replacement mutations owing to their codon usage and (Lossos *et al.*, 2000) suggested the use of a multinomial, rather than binomial, model to determine significance. The failure to account for mutational hotspots and biases in mutational outcomes was suggested to lead to inaccuracies in these approaches (Bose and Sinha, 2005). This led to the proposed method by (Dahlke *et al.*, 2006) which extended prior literature to model hotspots using trinucleotides mutability scoring based on observed CDR and FR sequences to compare the accumulation of replacement mutations in the CDR in the context of the overall level of IGHV mutation.

Comparing Immunoglobulin Repertoires

The ability to compare repertoires, either from different samples from a single individual, or between different individuals generally relies upon comparing various metrics calculated after repertoire partitioning and annotation of clonal relationships and SHM spectra. For example, the frequency at which different gene segments are utilized, the frequency of somatic hypermutation, the isotype subclass utilization or characteristics and distributions of the clonal expansions. Frameworks for statistical comparisons of overall repertoires have been historically lacking. Two recently published frameworks to compare repertoires are the repertoire dissimilarity index (RDI) (Bolen *et al.*, 2017) and the MaxSnippetModel (Ostmeyer *et al.*, 2017). RDI is a non-parametric method to quantitatively compare repertoires by average variance in gene segment utilization through a combination of bootstrapped sub-sampling and simulation (Bolen *et al.*, 2017). In comparison, the MaxSnippetModel focusses on determining differences in CDR3 sub-motif composition between repertoires from different disease contexts by attempting to statistically classify sequences by representing CDR3 AA 'snippets' (overlapping sub-strings of fixed length) sequences as vector-based representation of AA properties using Atchely factors (Ostmeyer *et al.*, 2017). A TensorFlow implementation is used to score the snippet Atchely factors using logistic modelling to define the maximum score for each sample before model fitting using gradient optimization for classification.

Analysis Pipelines for Repertoire Data Analysis

A variety of immunoglobulin repertoire datasets are available from public repositories. A sampling of public immunoglobulin repertoire sequence datasets is provided in Table 2. There is no single approach to the analysis of repertoire data. The approach taken will often depend upon the source of the data sequenced, the sequencing technology used, the computational skills of the user, and the research question they are seeking to. Many toolkits that implement end-to-end pipelines for analysis are now available with extensive use-case documentation, for example MiXCR (see Relevant Websites section), Immcantation (see Relevant Websites section) or ImmuneDB (see Relevant Websites section).

Table 2 Examples of publically available human immunoglobulin repertoire datasets

Accession	Accession type	Technology	Description

In the interest of highlighting the general components of repertoire data analysis pipelines an example of the basic processing steps from raw Illumina MiSeq paired end sequenced library of cDNA amplicons generated from primers positioned in the IGHV and IGHC to post-processed data using stand-alone tools would be as follows:

- **Pre-processing:** Merging of read pairs (eg. PEAR (Zhang *et al.*, 2014), de-multiplexing of barcodes and extraction of UMIs (eg. UMI-tools (Smith *et al.*, 2017)) and read trimming to remove primers and adaptors and quality filtering (eg. trimmomatic (Bolger *et al.*, 2014))
- **Partitioning:** Partitioning of merged read pairs using stand-alone instance of IgBLAST (Ye *et al.*, 2013) using either the IMGT reference sets of IGHV, IGHD and IGHJ segment or customized germline datasets.
- **Isotype calling:** Using either script-based string matching (eg. perl or python) or BLAST alignment (Camacho *et al.*, 2009) to determine which isotype subclass is associated with each VDJ based on the expected CH1 exon sequence governed by the IGHC primer location.
- **Parsing:** Scripting to parse key features from the IgBLAST output such as gene segment calls, mutations, N/P nucleotides and CDR/FRs and to integrate the isotype and other metadata.
- **Clone building:** CDR3 sequence subset based on the subject, IGHV, IGHJ and CDR3 length may be clustered using tools such as cd-hit (Fu *et al.*, 2012) or uclust (Edgar, 2010) to infer clonally related sequences within an individual response. Similar clustering methods can be used across responses from different subject to define convergent IGH signatures.
- **Post-processing:** Custom databases may be used for storage to serve as a basis for analysis or custom file formats generated. Scripting languages can be used to develop analysis to explore the features of interest within the dataset.

Current Challenges and Conclusions

Like any field in rapid change, the immune receptor repertoire sequencing field has lacked standardization as it has moved into the era of deep sequencing, however, this gap is beginning to be addressed (Yaari and Kleinstein, 2015; Breden *et al.*, 2017). Challenges exist around the development and implementation of frameworks for the standardization of data submission, data formats for tool input and output and in the incorporation of new data types into traditional resources.

The integration of repertoire sequencing datasets with other 'omics data derived from the same subject is becoming increasingly popular. For example, annotation of deeply sequenced repertoire data for antigen specificity through the use of monoclonal antibodies (Jackson *et al.*, 2014), or matching of transcript datasets to proteomic (Adamson *et al.*, 2017). Tools that provide researchers with a unified analysis of their various data types will become increasingly important as these gaps are currently filled by custom, in-house pipelines that link often disparate tools and toolkits to undertake analysis. Leveraging deep sequenced dataset for deep and machine learning applications is also expected to become increasingly informative as the variety, number and depth of datasets continues to increase.

Biographical Sketch

Dr Katherine J.L. Jackson: Dr Jackson is currently a Senior Research Officer at the Garvan Institute of Medical Research in Sydney, Australia. She completed her graduate studies at the University of New South Wales in Sydney, Australia on the detection of antigen selection signatures in immunoglobulin sequence datasets and has completed postdoctoral training at both the University of New South Wales and Stanford University, CA, USA. Her research applies immune repertoire sequencing methodologies to the study a variety of human immune responses including primary and secondary responses to vaccination and infection, allergy and autoimmunity, while also using exploring the immunogenetics of both humans and mice.

Epitope Predictions

Introduction

Hallmarks of the adaptive immune system are discrimination of self from non-self recognized as antigenic determinants or epitopes through concerted activation of antibody and cell-mediated primary or memory responses. A complex network of molecular and cellular interactions that includes antigen presenting cells, T cell and B cells regulates the steps from antigen processing, epitope presentation and recognition to memory recall (Litman *et al.*, 2010; Frank, 2002). One key question in epitope prediction is whether a predicted epitope will be immunogenic. Indeed theoretical estimates for MHC class I restricted T cell epitopes indicate that only 1 in 2000 peptides of non-self antigens may induce a dominant CTL response (Yewdell and Bennink, 1999).

T Cell Epitopes

Antigen presenting cells process proteins into peptides that if recognized by T cells are called T cell epitopes. Two distinct pathways facilitate the processing of exogenous and endogenous (self and foreign) proteins into peptides which were comprehensively reviewed by Blum *et al.* (2013). Most peptides generated by proteolysis through 26S proteasome are transported by TAP (transporter associated with antigen processing) into the endoplasmic reticulum where they bind to MHC class I molecules. If the affinity of the peptides to MHC class I molecules is sufficiently high, stable peptide-MHC-I complexes are transported through the Golgi apparatus to the cell surface where they are recognized by T-cell receptors (TCR) of CD8⁺ T cells (Fig. 1). In contrast, MHC class II molecules usually bind in the endosome to peptides derived from lysosomal proteolysis of exogeneous proteins trafficked by phago- and endocytosis. Peptide-MHC II complexes are then transported in endosomal vesicles to the cell surface where they are recognized by TCR expressed on CD4⁺ T cells (Fig. 2). Although the binding of the peptides to MHC is crucial in

Fig. 1 Processing, presentation and recognition of MHC class I-restricted T cell epitopes. Modified from Fig 17.21 (a) in Karp, G., 2008. Cell and Molecular Biology. Concepts and Experiments, fifth ed. Asia: John Wiley & Sons (Asia) Pte. Ltd.

Fig. 2 Processing, presentation and recognition of MHC class II restricted T cell epitopes. Modified from Fig 17.21 (a) in Karp, G., 2008. Cell and Molecular Biology. Concepts and Experiments, fifth ed. Asia: John Wiley & Sons (Asia) Pte. Ltd.

defining whether peptides may become epitopes, cross-presentation of peptides generated from phagocytosed exogenous proteins by MHC class I or endogenous proteins processed in the lysosome by MHC class II complicates matters in epitope prediction-assisted vaccine design. Cross-priming of naïve $CD8^+$ T cells mediated by cross-presentation is just one example where the choice of epitopes in a vaccine will affect primary and secondary T-cell responses (Grotzke *et al.*, 2017). Since epitope-based vaccines are meant to mimic the natural protective immunity that activates the functions of both T and B cells (Fig. 3) we need to consider also B cell epitopes.

B Cell Epitopes

B cell epitopes do not require processing and are predominantly of conformational or discontinuous nature (Barlow *et al.*, 1986; Greenbaum *et al.*, 2007). The B cell epitope is a specific 3D surface area of an antigen that is recognized by the paratope, the antigen-binding part of the antibody (Sela-Culang *et al.*, 2013). Antibodies represent the secreted form of B-cell receptors (hence B cell epitopes) which are produced by mature B cells, the plasma cells (Fig. 3). The antibodies produced by plasma cells are the result of a somatic hypermutation process of the complementary determining regions (CDRs) that increases the antibody affinity to the antigen (affinity maturation) (Schroeder and Cavacini, 2010; Neu and Wilson, 2016). Unlike T cell epitope predictions the conformational nature of the B cell epitopes and conformational diversity of antibodies themselves, in addition to conformational changes induced in both antibodies and epitopes when they bind to each other, pose an additional challenge in identifying immunogenic candidate B cell epitopes. Unsurprisingly, advances in predicting B cell epitopes are less pronounced than for T cell epitopes although the problem of conformational epitopes has been known since 1986 when the first crystal structure of a lysozyme-antibody complex was published (Barlow *et al.*, 1986).

Background

Immunogenicity of Epitopes

In both T and B cell epitope predictions of pathogen-derived proteins the goal is to identify potential immunogenic epitopes that induce a protective immune response. In case of T cell epitopes, peptides that are predicted to bind with high affinity (good binders) to MHC molecules are indeed very often immunogenic. Yet the MHC binding affinity remains a surrogate that does not provide clues about the type of T cell response an epitope may trigger. Co-stimulatory signals mediated by expression of various members of the cluster of differentiation (CD) family on both antigen presenting cells and T cells will determine which signaling pathway downstream of the TCR-peptide-MHC complex are activated, and hence whether the epitope triggers an effector T cell response or a suppressive, regulatory T cell response. Thus future assessments of predicted epitopes towards immunogenicity,

Fig. 3 Interaction of activated T helper cells activates B cells which differentiate into memory and plasma cells. The latter secrete antigen-specific antibodies. Modified from Fig 17.10 (a) in Karp, G., 2008. *Cell and Molecular Biology. Concepts and Experiments*, fifth ed. Asia: John Wiley & Sons (Asia) Pte. Ltd.

particularly in context of human vaccine development, should take into account the data derived from systems biology approaches (Querec *et al.*, 2009) and biomarker assays (Rappuoli and Aderem, 2011) in the context, dynamics and quality of a protective immune response to further boost the efficacy of data-driven predictions.

Overview of Epitope Predictions

Epitope predictions utilize statistical, machine learning or structural models derived from experimental data as reviewed by Soria-Guerra *et al.* (2015). Early epitope prediction methods BIMAS (Parker *et al.*, 1994) and EpiMatrix (Schafer *et al.*, 1998) were based on quantitative matrices (QM) or binding motifs (SYFPEITHI) (Rammensee *et al.*, 1999) that capture simple linear relationships of binding and non-binding data. Both methods are limited by the number of available experimental binding and non-binding data for a specific MHC allotype to derive a binding motif based on amino acids observed at peptide residue positions or to score a peptide's binding potential using position-dependent coefficients of amino acids. The limitations of quantitative matrices including overfitting, are balanced in practice by their easy implementation and use combined with an acceptable accuracy for selected MHC allotypes (Schönbach *et al.*, 2002; De Groot *et al.*, 2002).

The continuous growth of data enabled the application of more sophisticated methods utilizing artificial neural networks (ANN) (Adams and Koziol, 1995), hidden Markov models (HMM) ranging from fully connected HMMs to profile HMMs (Mamitsuka, 1998; Brusic *et al.*, 2002; Zhang *et al.*, 2006; Larsen *et al.*, 2006), and support vector machines (SVM) (Zhang *et al.*, 2007; Jacob and Vert, 2007; Chen *et al.*, 2007) that are adept in extracting and processing complex nonlinear relationships in peptide-MHC binding or B cell epitope data to derive predictive models. The predictive power of these models largely depends on the quantity and quality of (unbiased) annotated data. Immune Epitope Database (IEDB) (Vita *et al.*, 2014), a manually curated database of experimentally characterized immune epitopes has been instrumental in providing since 2005 high-quality data for training and testing datasets. Successful application of these data-driven methods that reduced experimental time and costs spurred further improvements towards increasing the accuracy of CTL epitope predictions by combining different individual prediction-based models followed by integrating top-predicting scores to derive a consensus score (consensus methods) (Moutafsi *et al.*, 2006). Similarly, the integration of predictions for distinct processes such as proteasomal processing, TAP binding and peptide-MHC binding while decreasing the dependency on MHC allotype-specific binding data as implemented in NetCTL-pan (Stranzl *et al.*, 2010) improved the predictive power.

Structure-based methods (Patronov and Doytchinova, 2013) yield high-quality quantitative predictions of peptide-MHC binding affinities based on free Gibbs energy calculations that take into account the interactions and distances between atoms of peptide and MHC amino acid residues. Threading of peptides predicted to bind to MHC is based on the computationally intensive free energy calculations of individual interactions (Logean and Rognan, 2002) or pairwise interactions using an energy potential

matrix (Schueler-Furman *et al.*, 2000). Quantitative structure-activity relationship (QSAR) methods that are employed in drug discovery, assuming similar molecular structures result in similar activities, analyze differences in free energy and structures (Doytchinova and Flower, 2002). The limited number of available high quality structures restricts the applicability of structure-based methods particularly for B cell epitope predictions.

The performance of prediction methods is evaluated by applying Pearson correlation, Matthews correlation coefficients or receiver operating characteristic (ROC) analyses which includes positive-predictive value (PPV), negative-predictive value (NPV), area under the receiver operating characteristic curve (A_{ROC}), sensitivity (SE), specificity (SP) or root mean squared deviations (RMSD) of distances in Å for structure predictions (Yang and Yu, 2009; Hattotuwigama *et al.*, 2007). SE provides the ratio of correctly predicted real positives, whereas SP for example, correctly predicted true negatives indicate the quality of predictions. PPV and NPV provide an overall success rate as proportions of true positives (negatives) of all positive (negative) predicted, whereas the A_{ROC} value reflects the overall quality of predictions within SE and SP value ranges. The A_{ROC} value is a robust measure as long as the number of positives and negatives in a test set are not extremely lop-sided. When no independent test data sets are available leave-one-out cross-validation (LOOC) (Sammut and Webb, 2010) is often used. LOOC may indicate an acceptable performance of a tool that becomes unacceptable when applied to a new data set.

Approaches

T Cell Epitope Prediction

T cell epitope predictions can be divided into integrated, MHC-pan and allotype-specific binding, TAP binding, proteasomal cleavage, and a few miscellaneous approaches which are represented by 38 publicly available, mostly web accessible tools shown in Table 1. Each tool is summarized by its name, URL, applicable species, and salient features including limitations, performance and methods applied to provide a convenient desk reference for choosing a T cell epitope prediction tool.

Independent of the approach categories the majority of tools rely on the application of QM, ANN, SVM, consensus or hybrid methods. An ANN is a network of interconnected nodes whose connections carry numeric data that are trained by weighting the connections (Honeyman *et al.*, 1998). Prior to using an ANN for peptide sequences the sequences must be transformed to numeric descriptors to input into the network layers. Popular ANN-based prediction tools include MULTIPRED2 (Zhang *et al.*, 2011a), NetMHC 4.0 (Andreatta and Nielsen, 2015) and NetMHCpan 3.0 (Nielsen and Andreatta, 2016) for MHC class I and NetMHCII 2.2 (Nielsen and Lund, 2009) and NetMHCIIpan 3.1 (Andreatta *et al.*, 2015) for MHC class II peptide binding.

SVMs comprise machine learning algorithms that classify complex data by placing it into a multidimensional space and constructing a hyperplane through an appropriate kernel function. Representative tools using SVM are TAP binding predictor TAPreg (Diez-Rivero *et al.*, 2010), MHC class II peptide binding predictor MHC2SKpan (Guo *et al.*, 2013) and T cell epitope immunogenicity predictor Repitope (Ogishi and Yotsuyanagi, 2017).

Several MHC-pan (PSSMHCpan (Liu *et al.*, 2017) and TEPITOPEpan (Zhang *et al.*, 2012)) and allotype-specific tools (PickPocket 1.1 (Zhang *et al.*, 2009), HLaffy (Mukherjee *et al.*, 2016)) and PREDIVAC 2.0 (Oyarzún *et al.*, 2013) use QM-based methods that assign coefficients for each amino acid in a peptide frame and discriminate potential binders from non-binders through the derived peptide score. The only QM-based tool that successfully integrated proteasomal processing, TAP, MHC class I and II binding prediction is TEpredict (Antonets and Maksyutov, 2010) whereas ANN- and QM-based NetCTLpan 1.1 (Stranzl *et al.*, 2010) do not cover MHC class II.

Integrated approaches that are based on the consensus of independent methods tend to outperform single methods. NetMHCcons 1.1 which couples NetMHC 3.4, NetMHCpan 2.8 and PickPocket 1.1 methods is a leading example (Karosiene *et al.*, 2012).

The only MHC class II allele-specific candidate epitope prediction tools that utilize structure-based methods (Yao *et al.*, 2013) are EpiDOCK (Atanasova *et al.*, 2013) and EpiTOP (Dimitrov *et al.*, 2010a; Dimitrov *et al.*, 2010b). EpiDOCK uses docking score-based quantitative matrices to evaluate the binding potential of overlapping nonamer peptides generated from an input sequence to five HLA class II DPA/DBP, six DQA/DQB and 12 DRB1 proteins. EpiTOP employs QSAR-derived quantitative matrices that encode both peptide and HLA protein pocket interactions derived from 12 HLA-DRB1 allotypes to predict peptide-HLA-DRB1 binding.

Two tools, categorized under miscellaneous approaches use hybrid SVM and motif methods to identify potential T-helper cell epitopes by predicting cytokine-inducing peptides. IL4Pred (Dhanda *et al.*, 2013a) and IFNepitope (Dhanda *et al.*, 2013b) predict interferon gamma- and interleukin 4-inducing MHC class II peptides, respectively.

B Cell Epitope Prediction

The conformational and linear B cell epitope prediction approaches comprising 21 web accessible tools are summarized according to their characteristics including performance, limitations and methods in Table 2.

Representatives of conformational epitope prediction approaches using structure-based methods are Discotope 2.0 (Kringelum *et al.*, 2012) and BEpro (Sweredoski and Baldi, 2008b). Discotope 2.0 uses amino acid residue propensity scores within a defined sphere whereas BEPro applies an amino acid propensity scale in combination with side chain orientation and solvent accessibility properties.

Table 1 T cell epitope prediction approaches

Name and URL	Species	Functionality and Performance	Limitations	Method
<i>Integrated approaches</i>				
NetCTLpan 1.1 http://www.cbs.dtu.dk/services/NetCTLpan/	Hosa, Patr, Mamu, Susc, Mumu, Gogo, Bota	Integrates prediction of proteasomal cleavage, TAP and MHC class I binding affinity; A_{ROC} : 0.920–0.977 (depending on data); (Stranzl <i>et al.</i> , 2010).	Predictions for 8–11 mer; at most 5000 sequences per submission and each sequence must be <20,000 amino acids; maximum 20 MHC allotypes per submission.	ANN and matrix (matrix for TAP).
NetTepi 1.0 http://www.cbs.dtu.dk/services/NetTepi/	Hosa	Integrates peptide-MHC binding affinity, peptide-MHC stability and TCR propensity; prediction values are weighted sum or % rank; sorted by combined, affinity, stability, TCR propensity scores; $AUC_{0.1}$: 0.9285–0.9305 (depending on the combined model) (Trolle and Nielsen, 2014).	13 HLA allotypes; 8–14mer peptides; at most 5000 sequences per submission and each sequence must be <20,000 amino acids; T cell propensity tool was validated only on 9mer peptides.	ANN and matrix.
NetMHCcons 1.1 http://www.cbs.dtu.dk/services/NetMHCcons/	Hosa, Patr, Mamu, Susc, Mumu, Gogo, Bota	Integrates methods of NetMHC, NetMHCpan and Pickpocket; predictions for 8–15mer peptides; prediction values in nM IC_{50} and % Rank; sorting by predicted binding affinity; PCC: 0.23–0.72 (depending on the group of allotypes) (Karosiene <i>et al.</i> , 2012).	101 MHC I allotypes; at most 5000 sequences per submission and each sequence must be <20,000 amino acids; maximum 20 MHC allotypes per submission.	Consensus method: ANN, pan-specific ANN, and matrix.
RANKPEP http://imed.med.ucm.es/Tools/rankpep.html	Hosa, Mumu	Cleavage prediction; immunodominance filter; molecular weight filter; predictions can be made from MSA; > 80% of CD8 ⁺ T cell epitopes are among top 2% of scoring peptides; 3–10% threshold was required to predict 80% of CD4 ⁺ T cells epitopes; (Reche <i>et al.</i> , 2004).	102 MHC I and 80 MHC II allotypes; predictions for MHC I binder are limited 8–11mer peptide; matrices are limited by the quality of sequences.	Matrix and SVM (Immuno-dominance).
NetCTL 1.2 http://www.cbs.dtu.dk/services/NetCTL/	Hosa	Integrates HLA class I binding, C terminal cleavage, TAP transport efficiency; (depending on the threshold); A_{ROC} : 0.941, sensitivity: 72% (among 5% top-scoring peptide) (Larsen <i>et al.</i> , 2007).	12 HLA supertypes; predicts only 9mer epitopes.	ANN (HLA binding and C terminal cleavage) and matrix (TAP transport efficiency).

ProPred1 http://crrdd.osdd.net/raghava/propred1/	Hosa; Mumu	Prediction of the standard proteasome and immunoproteasome cleavage sites; identification of MHC binders with cleavage sites at C terminus; output displayed in different formats; allows subsequence analysis; accuracy: 38–80% for HLA-A*0201, 70–80% for H2-Kb (depends on the threshold); (Singh and Raghava, 2003).	47 MHC I allotypes; only 9mer peptides are predicted; over-generalized – the matrices were obtained for enolase-1 protein.	Matrix.
nHLAPred http://crrdd.osdd.net/raghava/nhlapred/	Hosa, Mumu	Average accuracy for hybrid approach: 92.8%; prediction of the standard proteasome and immunoproteasome cleavage sites; identification of MHC binders with cleavage sites at C terminus; (Bhasin and Raghava, 2007).	67 MHC I allotypes; only nonamer peptides.	ANN and matrix or matrix only.
MULTIPRED 2.0 http://cvc.dfci.harvard.edu/multipred2/	Hosa	Allows input of pre-calculated viral proteomes; employs NetMHCpan and NetMHCIIpan as predictive engines; heatmaps are generated to visualize results; (Zhang <i>et al.</i> , 2011).	26 HLA class I and II supertypes; 8–11 mer peptides for HLA I and 9mer peptides for HLA II.	ANN.
TepiTool (Pipeline) http://tools.iecb.org/tepitool/	Hosa, Patr, Mamu, Susc, Mumu, Gogo, Bota and others	Integrates several predictive tools; predicts MHC I and MHC II binders; allow to select most frequent allotypes; different types of filtering, such as percentile rank, absolute rank, based on IC ₅₀ (Paul <i>et al.</i> , 2016).	Predicts 8–14mer epitopes.	Includes but not limited to consensus, ANN, and matrix methods.
MHCPred 2.0 http://www.ddg-pharmfac.net/mhcpred/MHCPred/	Hosa, Mumu	Two models of prediction: amino acids contribution; amino acids + their interactions; anchor positions (maximum 4) can be chosen; predicts affinity to TAP; (Guan <i>et al.</i> , 2006).	17 MHC class I and II allotypes; sequences are limited to 1000 residues; only plain format is supported.	Matrix.
FRED 2.0 (Pipeline) http://fred-2.github.io/	N/A	HLA typing, epitope prediction, epitope selection, and epitope assembly; implemented in Python; provides unified access to different epitope prediction tools and databases; (Schubert <i>et al.</i> , 2016).	Difficult to execute for unfamiliar users; requires separate installation of several external tools from Center for Biological Sequence Analysis, Technical University of Denmark.	Python-based framework.
TEpredict http://tepredict.sourceforge.net/downloads.html	N/A	Predicts MHC I and MHC II binders, proteasomal and immunoproteasomal processing, peptide and TAP binding;	Considers only 9mer peptides.	Matrix.

(Continued)

Table 1 Continued

Name and URL	Species	Functionality and Performance	Limitations	Method
SVMHC (works only via EpiToolKit pipeline) https://abi.inf.uni-tuebingen.de/Services/SVMHC	Hosa, Mumu	sensitivity: 50–80%; specificity: 75–99%; (Antonets and Maksyutov, 2010). Allows accessions/database identifiers as input; analysis of single amino acid polymorphism; different output views; (Donnes and Kohlbaicher, 2006).	Predictions for 8–10 mer peptides; 26 MHC I allotypes from MHCPEP, 24 MHC I allotypes from SYFPEITHI and 51 MHC II allotypes; only one sequence per submission; thresholds cannot be set by users.	SVM (MHC I) and matrices (MHC II).
PickPocket 1.1 http://www.cbs.dtu.dk/services/PickPocket/	Hosa, Patr, Mamu, Susc, Murmu, Gogo, Bota	Robust when data is scarce and when the similarity to MHC molecules with characterized binding specificities is low; PCC: 0.26–0.6 (depending on the evaluated set) (Zhang <i>et al.</i> , 2009).	8–12mer peptides; > 150 MHC I and II allotypes; at most 5000 sequences per submission and each sequence must be < 20,000 amino acids; maximum 20 MHC per submission.	Matrix.
MetaMHCpan http://datamining-iiip.fudan.edu.cn/MetaMHCpan/index.php/pages/view/info	Hosa, Mumu	Meta-server with different predictive methods (Xu <i>et al.</i> , 2016).	8–11mer peptides for MHC I and 9–25mer peptides for MHC II; 41 MHC I and > 600 MHC II allotypes.	Matrix, SVM, and multiple instance learning method.
<i>MHC I pan approaches</i> NetMHCpan 3.0 http://www.cbs.dtu.dk/services/NetMHCpan/	Hosa, Patr, Mamu, Susc, Murmu, Gogo, Bota	91% of ligands are recovered at a rank threshold of 2% with a specificity of 98%; A _{ROC} : 0.83–0.89; (depending on the epitope length); (Nielsen and Andreatta, 2016).	172 MHC I molecules; 8–14mer peptides; at most 5000 sequences per submission and each sequence must be < 20,000 amino acids; maximum 20 MHC allotypes per submission.	ANN.
PSSMHCpan https://github.com/BGI2016/PSSMHCpan	Hosa	A _{ROC} : 0.94, accuracy: 85%; able to predict neoantigens; 8–25 mer peptide length prediction; (Liu <i>et al.</i> , 2017).	87 HLA class I allotypes.	Matrix.
<i>MHC I allotype-specific approaches</i> NetMHC 4.0 http://www.cbs.dtu.dk/services/NetMHC/	Hosa, Patr, Mamu, Susc, Murmu, Bota	A _{ROC} : 0.882–0.895; (depending on the peptide epitope length); (Andreatta and Nielsen, 2015).	122 MHC I allotypes; 8–13 mer peptides; at most 5000 sequences per submission and each sequence must be < 20,000 amino acids;	ANN.

HLaffy http://proline.biochem.iisc.ernet.in/HLaffy/?tab=1	Hosa	Estimates peptide affinity for HLA class I; accuracy: 92% and correlation: 0.85, for IEDB dataset accuracy: 82.5%; provides a histogram view; representative molecular models with favorable peptide-HLA residue interactions are available (Mukherjee et al., 2016).	maximum 20 MHC allotypes per submission. Only for 9mer peptides.	Matrix.
<i>MHC II pan approaches</i> NetMHCIIpan 3.1 http://www.cbs.dtu.dk/services/NetMHCIIpan/	Hosa, Mumu	Prediction values are given as IC ₅₀ (inhibitory concentration) and as % ranks; A _{ROC} : 0.80–0.90 for the binding between peptide and MHC; (Andreatta et al., 2015).	4 MHC II isotypes; at most 5000 sequences per submission and each sequence must be <20,000 amino acids; maximum 20 MHC per submission.	ANN.
TEPITOPEpan http://datamining-iiip.fudan.edu.cn/service/TEPITOPEpan/TEPITOPEpan.html	Hosa	Shows binding cores and percentile ranks; prediction for 9–25mer peptides; average A _{ROC} : 0.717–0.833 (depending on the dataset); predicts over 700 HLA-DR allotypes; (Zhang et al., 2012).	Limited to HLA-DR.	Matrix.
MHC2SKpan http://datamining-iiip.fudan.edu.cn/service/MHC2SKpan/info.html	Hosa	Predicts MHC class II peptide binding; A _{ROC} : 0.734–0.843 (depending on the dataset); (Guo et al., 2013).	9–25mer peptides; DRB only.	SVM.
PREDIVAC – 2.0 http://predivac.biosci.uq.edu.au/	Hosa	A _{ROC} : 0.842–0.872 for HLA II binding; A _{ROC} : 0.749 for CD4-T-cell epitopes; 883 HLA II allotypes; target population epitope predictions (Oyarzún et al., 2013).	DRB only.	Matrix.
<i>MHC II allotype-specific approaches</i> NetMHCII 2.2 http://www.cbs.dtu.dk/services/NetMHCII/	Hosa, Mumu	Predictions are given as % Rank and in nM IC ₅₀ values; A _{ROC} : 0.68–0.82 (depending on the dataset and method) (Nielsen and Lund, 2009).	28 MHC II allotypes; at most 5000 sequences per submission, each sequence must be <20,000 amino acids.	ANN.
EpiDOCK http://epidock.ddg-pharmfac.net/	Hosa	Identifies 90% true binders and 76% true non-binders; overall accuracy: 83% (Atanasova et al., 2013).	23 HLA II allotypes; only 9mer peptides are predicted; no sorting mechanism.	Matrix.
EpiTOP http://www.pharmfac.net/EpiTOP/	Hosa		12 HLA-DRB1 allotypes; only 9mer peptides are predicted;	Matrix.

(Continued)

Table 1 Continued

Name and URL	Species	Functionality and Performance	Limitations	Method
MHC2Pred http://crdd.osdd.net/raghava/mhc2pred/	Hosa, Mumu	Identifies 89% of known epitopes within top 20% of predicted binders (Dimitrov <i>et al.</i> , 2010a,b). Accuracy: > 78%; (Lata <i>et al.</i> , 2007).	allotype selection did not work at the time of testing. 42 MHC II allotypes; only 9mer peptides are predicted; inconvenient output format without sorting options.	SVM.
Propred http://crdd.osdd.net/raghava/propred/	Hosa	Output displayed in different formats; (Singh and Raghava, 2001).	51 HLA-DR allotypes.	Matrix.
HLA-DR4Pred http://crdd.osdd.net/raghava/hladr4pred/	Hosa	Accuracy: 86% and 78% for SVM and ANN, respectively. (Bhasin and Raghava, 2004b)	Only for HLA-DRB1*0401.	SVM and ANN.
<i>Proteasomal cleavage approaches</i>				
Pcleavage http://crdd.osdd.net/raghava/pcleavage/	N/A	Predicts proteasome cleavage sites; MCCs: 0.54 and 0.43 for <i>in vitro</i> and MHC ligand data respectively (Bhasin and Raghava, 2005).	The C-terminal of MHC ligands represents only a subset of cleavages that occur <i>in vivo</i> .	SVM.
NetChop 3.1 http://www.cbs.dtu.dk/services/NetChop/	Hosa	Predicts cleavage sites of human proteasome; two different methods: C-terminus and 20S; specificity: 48%, sensitivity: 81% MCC: 0.31 (Nielsen <i>et al.</i> , 2005).	At most 100 sequences and 100,000 amino acids per submission.	ANN.
<i>TAP binding approaches</i>				
TAPPred http://crdd.osdd.net/raghava/tappred/	Hosa	Predicts TAP-binding peptides; correlation coefficients: 0.88 (Cascade SVM) and 0.8 (SVM); cascade SVM uses features of amino acids along with sequence whereas SVM uses only sequence (Bhasin <i>et al.</i> , 2007).	N/A	SVM or Cascade SVM.
TAPreg http://imed.med.ucm.es/Tools/tapreg/	N/A	Predicts affinity of TAP binding ligands; maximum PCC: 0.89 ± 0.03 (Diez-Rivero <i>et al.</i> , 2010).	Data training was done on 9mer peptides only.	SVM.
<i>Miscellaneous T cell epitope related prediction approaches</i>				
Repitope https://github.com/masato-ogishi/Repitope	Hosa	Epitope immunogenicity prediction; accuracy: 70–80% (Ogishi and Yotsuyanagi, 2017).	Retrospective observational study; simplified assumptions biophysical-chemical nature of the TCR-peptide-MHC	SVM.

IL4pred http://crdd.osdd.net/raghava/il4pred/	N/A	Predicts interleukin 4-inducing MHC class II binders; maximum accuracy: 75.76% and MCC: 0.51 (hybrid method) (Dhanda <i>et al.</i> , 2013a).	interactions; limited to TCR-V beta. Training set consists of only 8–22mer peptides created without species considerations.	Motif, SVM or hybrid.
IFNepitope http://crdd.osdd.net/raghava/ifnepitope/	N/A	Prediction and design of interferon- γ inducing MHC class II binding peptides; maximum prediction accuracy of hybrid approach: 81.3% (MCC: 0.57) – 82.1% (MCC: 0.62) (depends on dataset) (Dhanda <i>et al.</i> , 2013b).	Analysis of positions-specific preference of residues was done only for a small number of peptides.	Motif, SVM or hybrid.
CTLPred http://crdd.osdd.net/raghava/ctlpred/	N/A	Predicts CTL epitopes; accuracy for QM, ANN and SVM: 70.0, 72.2% and 75.2% respectively; has combined and consensus prediction approaches; (Bhasin and Raghava, 2004a).	Training data contains only 9mer epitopes; small blind dataset (63 epitopes for 2 subgroups).	ANN, SVM and matrix.
MMBPred http://crdd.osdd.net/raghava/mmbpred/	Hosa, Mamu, Mumu	Prediction of mutated promiscuous binders e.g. increase/decrease of peptide-MHC binding; analyzes position and type of mutations (Bhasin and Raghava, 2003).	67 MHC I allotypes; only 9mer peptides are predicted; promiscuous binding prediction was not supported at the time of testing.	Matrix.

Abbreviations: ANN: artificial neural network, A_{ROC} or AUC: area under receiver operating characteristic curve, Bola: *Bos taurus*, Gogo: Gorilla gorilla, Hosa: *Homo sapiens*, HLA: human leukocyte antigen, Mamu: *Macaca mulatta*, MCC: Matthews correlation coefficient, MHC: major histocompatibility complex, MSA: multiple sequence alignment, Mumu: *Mus musculus*, Patr: *Pan troglodytes*, PCC: Pearson correlation coefficient, SVM: support vector machine, Susc: *Sus scrofa*, TAP: transporter associated with antigen processing, and QM: quantitative matrix.

Table 2 B cell epitope prediction approaches

Name and URL	Functionality and Performance	Limitations	Method
<i>Discontinuous/conformational epitope prediction approaches</i>			
SEPPA 2.0 http://lifecenter.sgst.cn/seppa2/	Subcellular localization of an antigen and host species are considered; A_{ROC} : 0.785–0.823 (depending on the host and localization of antigen protein); Jmol is used for visualization (Qi <i>et al.</i> , 2014).	Antigens with less than <25 residues were not considered.	Optimized logistic regression algorithm.
SEPIa https://github.com/SEPIaTool/SEPIa	A_{ROC} : 0.65; prediction is based on the amino acid sequence; amino acid features and sequence-based features are taken into account (Dalkas and Rooman, 2017).	Only window of 9 residues is used to test whether the middle residue is an epitope or not.	Gaussian Naïve Bayes and Random Forest algorithms based on 13 features.
DiscoTope 2.0 http://www.cbs.dtu.dk/services/DiscoTope/	A_{ROC} : 0.824 and 0.727 (for training and independent data sets) (Kringelum <i>et al.</i> , 2012).	Trained on a dataset with the total number of residues per epitope 9–22 and with the longest sequential stretch 3–12 residues per epitope.	Definition of the spatial neighborhood to sum propensity scores and half-sphere exposure as a surface measure.
EPSVR http://sysbio.unl.edu/EPSVR/	A_{ROC} : 0.597; evaluates 6 different features: residue epitope propensity, conservation score, side chain energy score, contact number, surface planarity score and secondary structure composition (Liang <i>et al.</i> , 2010).	Multiple epitopes in one antigen were not considered.	SVR with six attributes.
EPMeta http://sysbio.unl.edu/EPMeta/	A_{ROC} : 0.638 (Liang <i>et al.</i> , 2010).	Works only on Linux OS.	Consensus method for EPSVR, EPCES, Epitopia, SEPPA, BEpro and Discotope 1.2.
BEpro http://pepito.proteomics.ics.uci.edu/index.html	A_{ROC} : 0.754 and 0.683 (for Discotope and Epitome datasets respectively); Jmol is used for visualization (Sweredoski and Baldi, 2008b).	Propensity scale scores averaged over a window of exactly 9 residues; only PDB file format is supported.	Linear combination of amino-acid propensity scale, side chain orientation and solvent accessibility information using half sphere exposure values.
CBTOPE http://crrdd.osdd.net/raghava/cbtope/	Accuracy: 86.59%, A_{ROC} : 0.90, MCC: 0.73; prediction is based on the amino acid sequence using different window length patterns, standard binary and physicochemical profiles of pattern (Ansari and Raghava, 2010).	Lacks 3D structural output.	SVM.
EPCES http://sysbio.unl.edu/EPCES/	Sensitivity: 47.8%, Specificity: 69.5%, A_{ROC} : 0.632; evaluates residue epitope propensity, conservation score, side chain energy score, contact number, surface planarity score and secondary structure composition (Liang <i>et al.</i> , 2009).	Low accuracy for the bound structures.	Consensus scoring utilizing six different scoring functions.

Bpredictor https://code.google.com/archive/p/my-project-bpredictor/download	A_{ROC} : 0.633 and 0.654 for bound and unbound datasets respectively; impact of interior residues and different contributions of adjacent residues were considered (Zhang <i>et al.</i> , 2011a,b,c).	Window size: 3–15 residues.	Random-forest algorithm with distance based feature.
EpiSearch http://curie.utmb.edu/episearch.html	In most cases covers >50% of experimentally validated residues; Jmol is used for visualization (Negi and Braun, 2009).	In addition to the 3D structure of the antigen the input requires the set of mimotopes (up to 12 mer).	Patch analysis that identifies cluster of residues on the surface of antigen with similar physicochemical properties as in mimotopes.
PEP – 3D-Search http://kyc.nenu.edu.cn/Pep3DSearch/	MCC: 0.176, sensitivity: 36.4%, Precision: 69.5% (Huang <i>et al.</i> , 2008).	In addition to the 3D structure of the antigen the input requires the set of mimotopes; compatible only with Windows OS.	Mimotope-based analysis via ACO algorithm.
CEP http://196.1.114.49/cgi-bin/cep.pl	Accuracy: 75%; Jmol is used for visualization (Kulkarni-Kale <i>et al.</i> , 2005).	Simplified approach with few attributes.	Algorithm uses accessibility of residues and spatial distance cut-off.
<i>Linear B cell epitope prediction approaches</i> LBtope http://crdd.osdd.net/raghava/lbtope/	Able to identify mutation(s) in peptide and convert it/ them to the epitope; accuracy: 81% (54–86% depending on model and dataset); mutation tool is available to design better epitope or for de-immunization purpose (Singh <i>et al.</i> , 2013).	5–30mer epitope prediction.	SVM, using diverse features; binary profile, di-peptide composition and amino acid pair profile.
COBEpro http://scratch.proteomics.ics.uci.edu/	A_{ROC} : 0.606–0.829 (depending on the dataset); Predicts epitopes of any length (Sweredoski and Baldi, 2008a).	Prediction is limited to sequences of 1500 amino acids length.	SVM for the similarity measure based on the total number of identical substrings.
ABCPred http://crdd.osdd.net/raghava/abcpred/	Sensitivity: 67.14%, specificity: 64.71%, accuracy: 65.93%; has overlapping filter (Saha and Raghava, 2006).	10, 14, 16, 18, 20mer predicted epitope length in plain text format; developed with a small dataset derived from database BCiPEP (Saha <i>et al.</i> , 2005)	ANN.
SVMTriP http://sysbio.unl.edu/SVMTriP/	Precision: 54.1–57.1%, sensitivity: 68.5–80.1%, A_{ROC} : 0.674–0.702 (depending on the length of epitope); prediction combines tri-peptide similarity and propensity scores (Yao <i>et al.</i> , 2012).	10, 14, 16, 18, 20mer predicted epitope length; only one sequence per time in FASTA format; waiting time at the time of testing was 10–30 min.	SVM.
IgPred http://crdd.osdd.net/raghava/igpred/	Predicts B-cell epitopes that can induce a specific class of antibody; MCC: 0.44 (IgG), 0.7 (IgE), 0.45 (IgA), accuracy is around 80%; epitope mapping and motif scan functions are available (Gupta <i>et al.</i> , 2013).	4–20 mer epitopes.	SVM and WEKA. package tools.
Bcepred http://crdd.osdd.net/raghava/bcepred/		Only plain text format is supported; developed with a small dataset derived	Evaluation of different physicochemical scales by different method for each.

(Continued)

Table 2 Continued

Name and URL	Functionality and Performance	Limitations	Method
<i>Linear and discontinuous/conformational epitope prediction approaches</i> Epitopia http://epitopia.tau.ac.il/	Prediction accuracy for various properties: 52.92–57.53%; highest accuracy via combination of properties: 58.70% (Saha and Raghava, 2004). A_{ROC}: 0.6 (conformational) and 0.59 (linear); visualization through Jmol and RasMol; calculates immunogenicity for each solvent accessible residue for 3D structure input and for every amino acid for sequence input (Rubinstein <i>et al.</i>, 2009).	from database BCIPEP (Saha <i>et al.</i>, 2005) Immunogenicity of each residue is determined by analysis of physicochemical properties of three flanking residues.	Naïve Bayes classifier.
EllipPro http://tools.iedb.org/ellipro/	A_{ROC}: 0.732, sensitivity: 60.1%; Jmol and MODELLER program are available for visualization and prediction 3D structure (Ponomarenko <i>et al.</i>, 2008).	Generalize all proteins as ellipsoids.	Modified Thornton's method with residue (pI value) clustering
BepiPred 2.0 http://www.cbs.dtu.dk/services/BepiPred/index.php	A_{ROC} for structural epitopes: 0.62, A_{ROC} for linear epitopes: 0.574 (Jespersen <i>et al.</i>, 2017).	5–25mer epitope predictions; at most 50 sequences (max. 300,000 residues per submission, < 6000 residues/sequence	Random Forest algorithm

Implementations of machine learning algorithms for conformational epitope predictions are Epitopia (Rubinstein *et al.*, 2009), EPSVR (Liang *et al.*, 2010) and Bpredictor (Zhang *et al.*, 2011c). These tools utilize naïve Bayesian classifiers, SVM and random forest algorithm, respectively. A consensus method (Liang *et al.*, 2009) was developed for EPMeta (Liang *et al.*, 2010). EPMeta combines EPSVR, EPCES, Epitopia, SEPPA, BEpro and Discotope 1.2 predictions to predict surface residues as an epitope if two or more single tools have voted for it. None of the methods applied increased the predictive performances which range between A_{ROC} of 0.597 and 0.824, depending on the datasets tested, above moderate levels.

Sequence-based methods rely on amino acid sequence-based features to evaluate the probability of each residue to be a part of a conformational epitope (Sun *et al.*, 2013). CBTOPE is a SVM-based tool that applies standard binary and physico-chemical profiles of patterns (Ansari and Raghava, 2010). SEPIa employs naïve Bayesian classifier and random forest ensemble methods to classify residues using 13 different features (Dalkas and Rooman, 2017). Although sequence-based methods can be a solution for conformational epitope predictions the performance improvement of complex methods as implemented in SEPIa is minor compared to simpler methods.

Mimotopes are peptides selected from random libraries for their ability to bind to an antibody directed against a specific antigen. Since the mimicry relies on similarities in physicochemical properties and spatial organization (Moreau *et al.*, 2006) mimotope analysis methods applied to conformational epitope predictions require both mimotopes and a 3D structure of the target antigen as an input. The mimotopes are mapped to the surface of the antigen to identify the best sequence alignment, and predict potential epitope regions (Sun *et al.*, 2016). For example PEP-3D-Search searches for matching paths on an antigen surface with respect to the query mimotopes using an ant colony optimization algorithm (Huang *et al.*, 2008).

Linear epitope prediction approaches utilize SVM, ANN and random forest machine learning methods to evaluate multiple amino acid residue properties (Potocnakova *et al.*, 2016). The machine learning approaches have substituted older, poorly performing methods that used only amino acid propensity scores (Blythe and Flower, 2005). The features assessed include for example hydrophilicity, flexibility, turns, solvent accessibility and amino acid pair antigenicity scale (Yasser and Honavar, 2010). SVMTriP (Yao *et al.*, 2012), LBtope (Singh *et al.*, 2013) and COBEpro (Sweredowski and Baldi, 2008a) are representatives of SVM-based tools. ABCpred (Saha and Raghava, 2006) and Bepipred 2.0 (Jespersen *et al.*, 2017) are ANN and random forest-based tools, respectively.

A few tools allow the prediction of both conformational and linear B cell epitopes. ElliPro (Ponomarenko *et al.*, 2008) is based on the implementation of three different algorithms that treat a protein as an ellipsoid shape (Taylor *et al.*, 1983), derive a residue protrusion index using a modified Thornton method (Thornton *et al.*, 1986), and cluster neighboring residues according to their pI (isoelectric point) values. When tested on a conformational epitope dataset constructed from antibody-protein complex 3D structures ElliPro's performance was moderate (A_{ROC} 0.732). Naïve Bayes classifier-based Epitopia (Rubinstein *et al.*, 2009) performs slightly inferior for conformational (A_{ROC} 0.60) and linear (A_{ROC} 0.59) epitopes. Similarly modest performances were reported for BepiPred 2.0 with A_{ROC} 0.62 for conformational and A_{ROC} 0.574 for linear epitopes (Jespersen *et al.*, 2017).

MHC and Epitope Databases

Sustained public accessibility of curated high-quality data on HLA allele sequences, experimentally derived epitope and non-epitope data has enabled the development and improvement of epitope prediction tools. IMGT[®] (the international ImmunoGeneTics information system[®]) established in 1989 became the global reference in immunogenetics and immunoinformatics for immunoglobulins or antibodies, T-cell receptors, human and vertebrate major histocompatibility, immunoglobulin superfamily and related proteins of the immune system of vertebrates and invertebrates (Lefranc *et al.*, 2014).

SYFPEITHI, one of the oldest databases in the field had been utilized together with IEDB (Vita *et al.*, 2014) to develop T cell epitope prediction tools. SYFPEITHY includes more than 7000 peptides that bind to MHC class I and II molecules (Rammensee *et al.*, 1999). With increasing utility of IEDB and integration of epitope data SYFPEITHY became static in 2012.

IEDB stores data on more than 300,000 peptide epitopes including epitope information derived from antigen-antibody complex of PDB, and more than 2500 non-peptide epitopes. The epitope data is not restricted to human and mouse but includes also chimpanzee, macaque, cow and swine. Integrated epitope prediction tools for linear and discontinuous B cell epitopes such as ElliPro (Ponomarenko *et al.*, 2008) or the pipeline TepiTool pipeline (Paul *et al.*, 2016) for vaccine, diagnostic, therapeutic candidate epitope discovery render IEDB by far the most user-friendly and effective resource. Yet a prediction tool that identifies in one process candidate B and T cell epitopes still awaits its implementation.

Illustrative Examples or Case Studies

The applications of epitope predictions are as multifarious as immunoinformatics the field that rose from the beginnings in theoretical immunology to make an impact on vaccine research and development. A representative example is reverse vaccinology (Sette and Rappuoli, 2010). This strategy allows the rapid design of novel vaccines based on pathogen genome information used in epitope predictions. Guttierrez and collaborators have demonstrated successfully the design of an effective epitope-based vaccine against swine Influenza A virus through MHC class I and II restricted epitope prediction using PigMatrix (Gutiérrez *et al.*, 2016). The vaccinated pigs responded to virus re-stimulation, showing that the epitope-based vaccination gave rise to T cells that were cross-reactive in vitro with epitopes present in the whole virus.

Another important application of epitope predictions are personalized therapeutic vaccines with the aim to treat epithelial cancer and melanoma as reviewed by Bobisse *et al.* (Bobisse *et al.*, 2016). Typically, epitope predictions of mutated antigens (neonantigens) involves NetMHC or NetMHCpan to identify high-affinity candidate neo-epitopes for *in vitro* validation before stimulating and expanding a patient's tumor infiltrating lymphocytes *ex vivo* for use in adoptive cell therapy. Several clinical trials are ongoing for example a phase I study on a personalized melanoma neoantigen cancer vaccine that started in 2013 (see relevant websites). Although it is too early to pass judgement on the success or failure of the approach even negative data, provided they are published and shared, can help to improve predictions, particularly prediction methods for class II restricted epitopes which perform less accurately than for class I.

In a recent report by Anagnostou *et al.* (2017) epitope prediction had an essential role to elucidate the mechanism of resistance to immune checkpoint blockade drugs in cancer patients. The study of neoantigen evolution during immune checkpoint blockade in non-small cell lung cancer required to assess the immunogenicity of somatic mutations in tumors using wild-type and mutated peptides. NetMHCpan was used to predict the class I binding potential of each peptide, and NetCTLpan to evaluate antigen processing to classify epitopes and non-epitopes. Interestingly, candidate mutation-associated neoantigens with high HLA binding affinity disappeared, probably driven by immune-mediated elimination of cancer cells, thereby depriving patients the means to mount an effective functional immune response.

A lesser known application area of epitope prediction is graft-versus-host disease (GVHD) in organ transplantation research. Monitoring GVHD onset and prevention depends critically on the knowledge of minor histocompatibility antigen (MiHA) match/mismatch between donor and recipient. Van Bergen and collaborators used NetCTLpan to evaluate amino acid polymorphisms among 19 MiHAs for the potential to be targeted by alloreactive CD8 T cells in GVHD patients (van Bergen *et al.*, 2017). The approach yielded 13 new MiHA T cell epitopes.

Numerous other case studies ranging from allergen cross-reactivity, infectious diseases, autoimmunity to therapeutic proteins could be listed here that demonstrate the applicability of current epitope prediction methods in basic, applied and clinical research accompanied by savings in time and cost.

Results and discussion

One of the challenges in epitope prediction is the high polymorphism of MHC genes. Immuno Polymorphism Database IPD-HLA/IMGT (release 3.29.0, 2017) contains 12,544 HLA class I alleles and 4622 HLA class II alleles (Robinson *et al.*, 2014). In IEDB only 272 (2.17%) HLA class I and 247 (5.34%) HLA class II allotypes are associated with experimental peptide binding or T cell epitope data. Therefore allotype-specific prediction methods (e.g. QM-based methods) are not able to deal with MHC allotypes that are uncharacterized with regard to peptide binding. The first method that satisfactorily addressed the issue for HLA-A and -B allotypes was NetMHCpan (Nielsen *et al.*, 2007; Zhang *et al.*, 2011a,b,c) by combining all HLA sequence and peptide data as input into an ANN to derive general features between HLA sequences and peptides and make inferences on binding affinities. Although the initial method has been refined and overcame the problem of variation in peptide length (Lundegaard *et al.*, 2008) and potential multiple binding frames for MHC class II (NetMHCIIpan) it has been of limited use for various non-human primate, bovine and swine MHC where dissimilarities among MHC sequences exceeded the threshold for reasonably accurate epitope predictions. Considering the effects of MHC sequence and peptide data diversity and redundancy on the accuracy of epitope predictions (Kim *et al.*, 2014) Mattsson *et al.* proposed in 2016 an MHC-pan method improvement that relies on MHC class I similarity redundancy reduction rather than peptide similarity by using pseudo-sequences derived from the binding cleft amino acid environment of each MHC class I molecule in the input space (Mattsson *et al.*, 2016). In principle, the method could be extended to all MHC class II allotypes opening the possibility to integrate OptiType HLA-typing from next-generation sequencing data (Szolek *et al.*, 2014) with epitope prediction for patient-specific therapeutic vaccine or in transplantation.

Despite the limitations of QM-based methods compared to ANN-based methods, they still yield robust results as demonstrated by De Groot and collaborators who have applied a genome-to-vaccine approach to design (not produce) an HLA class I and II epitope-based vaccine for avian H7N9 influenza using EpiMatrix in 20 h (De Groot *et al.*, 2013). The integration of EpiMatrix and JanusMatrix (Moise *et al.*, 2013), a prediction tool which allows to evaluate potential undesired cross-reactivity of predicted epitopes with human proteins or commensal gut bacteria that may trigger autoimmune responses into iVax (Moise *et al.*, 2015) improves the selection of epitope candidates to be tested for a vaccine. Unfortunately iVax is not an unrestricted-access tool which limits its spread and use, and may trigger future improvements of unrestricted accessible ANN-based tools emulating the JanusMatrix concept.

The performance of B cell epitope predictions is limited by the lack of a sufficiently accurate propensity scales for sequence-based methods and the scarcity of structural data of antigen-antibody complexes. For instance the training data sets of EPSVR and Discotope 2.0 comprised only 48 and 75 complexes, respectively. Therefore it is not too surprising that experimental validations of predicted B cell epitopes result in an average accuracy of 60% (Bergmann-Leitner *et al.*, 2013). Since NMR or X-ray crystallographic antigen-antibody and unbound structural data will increase only slowly, the development of new hybrid and meta-learning methods incorporating qualitative and quantitative features extracted from data generated by experimental methods of lower cost and effort such as phage-display library screening and "quality of antibody response" workflows that generate data of antibody binding from surface plasmon resonance (Davidoff *et al.*, 2015) and hydrogen deuterium exchange data combined with mass spectrometry (Yang *et al.*, 2016) are likely to improve the performance of B cell epitope predictions in the near future.

Epitope prediction tools are an integral part of the reverse vaccinology approach, yet a straightforward performance assessment similar to Critical Assessment of Structure Prediction (CASP) (Moult *et al.*, 2014) has not been conducted so far. CASP has helped to raise the accuracy of homology models and their acceptance as *bona fide* structural information source. In 2006 a NIAD B cell epitope prediction tool workshop (Greenbaum *et al.*, 2007) recommended the creation of annotated datasets and the development of methods and metrics to assess the prediction tools. IEDB has been very successful in assembling richly annotated T and B cell epitope data including negative non-epitope data. The latter were found to be biased towards short non-B-cell epitopes which negatively affected the performance of B cell epitope predictions when included in testing data sets (Rahman *et al.*, 2016). Yet, we are still lacking a community-based consensus procedure and minimal standards to assess the prediction tools. The establishment of a Critical Assessment of Epitope Predictions (CAEP) initiative is overdue to guide the improvement of predictions tools.

Future Directions

The success of epitope predictions particularly for HLA class I T cell epitopes has been largely driven by data and their level of integration with the current state of knowledge of immunological processes and host-pathogen interactions. Knowledge gaps in the details of immunological processes that define relations and differentiation dynamics of effector and memory T cell pools, and central and peripheral tolerance represent just two bottlenecks among others that require many more experimental data to advance predictive methods. At present we can identify immunogenic epitope candidates, but not optimal protective ones. For example, more work and data on molecular structures, TCR and BCR repertoire data are needed to predict cross-reactive and -neutralizing epitopes that will not be reduced in efficacy nor trigger autoimmunity when a pathogen is encountered two or more times.

Rational vaccine design and evaluation resembles in its temporal and mechanistic order of steps a biological pathway with epitope prediction positioned fairly upstream. Efforts to improve connectivity and feedback among individual components including epitope prediction may come to fruition on proof-of-concept level within the next five to ten year if concerted and standardized generation and collection of longitudinal data downstream of epitope predictions on gene and protein expression levels, protein-protein interactions and pathways, pathogen and antigen variation is funded and performed. The Human Vaccines Project (Koff *et al.*, 2014) a nonprofit public-private project that aims to elucidate the molecular cellular principles of vaccine-induced immunity is a promising high-impact initiative to enhance rational vaccine design. Translation into effective and affordable preventive vaccines for complex targets such as tuberculosis or HIV and therapeutic cancer vaccines may take longer because research progress on the effects and impact of natural genome and transcriptome variations in populations, and impact of environmental factors for example metals and chemicals, on the development, functioning and ageing of the immune system is slower. Areas deserving more attention include the development of algorithms to predict non-protein epitopes e.g. carbohydrates that are not unimportant for vaccines.

Closing Remarks

In the hierarchy of epitope prediction performance HLA class I binding predictions occupy the top position. Basically we can predict with current systems for any classical HLA class I allotype T cell epitope candidates. Second ranked are MHC class I-restricted T cell epitope predictions for chimpanzee, macaque, cow and swine. Therefore the development and actual use of epitope-based veterinary vaccines might precede the ones for human vaccines. Third ranked are predictions of HLA class II DR- and DQ-restricted epitope candidates. There is still room for significant improvements with regard to correctly identifying the core binding residues and increasing the number of experimental data for less studied allotypes, especially for HLA-DP. At the bottom of the performance hierarchy are B cell epitope predictions. This fact is expected to incentivize the development of both new experimental and data-driven computational methods that are anticipated to lift the accuracy and efficacy of B cell epitope predictions to acceptable levels until 2025.

Biographical Sketch

Roman Kogay is an undergraduate student at School of Science and Technology, Department of Biology, Nazarbayev University. His research interests include application of bioinformatics in metabolomics, genomics, proteomics and biomedical sciences. After graduation he hopes to pursue a doctoral degree.

Christian Schönbach is Professor at Graduate School of Medical Sciences, International Research Center for Medical Sciences, Kumamoto University. Prior to joining Kumamoto University he was Professor at School of Science and Technology, Department of Biology, Nazarbayev University (2013–2016). His research and teaching interests revolve around bioinformatics, genomics and immunology. Since 2010 he is serving the bioinformatics community of Asia-Pacific Bioinformatics Network (APBioNet) in various leadership roles.

Immunoglobulin Clonotype and Ontogeny Inference

Introduction

The adaptive immune response functions mainly through B and T lymphocytes. B lymphocytes express immunoglobulins (Igs, aka antibodies), which specifically bind antigens on surfaces of pathogens and neutralize them. Specificity towards such a large pool of threats is achieved by the diversity and dynamics of Ig repertoires. The DNA encoding for Igs comes from random selection of the variable (V), diversity (D), and joining (J) genes, through somatic rearrangement. In addition to the combinatorial diversity coming from the choice of V, D, and J genes, further diversity is added at the boundaries where the segments are joined, by imprecise excision and addition of random nucleotides, resulting in a staggering receptor diversity of up to 10^{11} different B cell clones in each human (see Fig. 1) (Boyd *et al.*, 2010, 2009; Murphy and Weaver, 2016; Weinstein *et al.*, 2009).

Following initial antigen recognition, B cells further undergo cycles of affinity maturation, during which their rearranged Ig gene loci are mutated in a process called somatic hypermutation (SHM), and cells with increased affinity to the antigen are selected for clonal expansion. This results in improved affinity of the Igs to the antigens, and the whole process is referred to as affinity maturation. The outcome of affinity maturation is short- or long-lived plasma cells secreting Igs, and short- or long-lived memory B cells.

Thus, the Ig repertoire of an individual stores information about current and past threats that the body has encountered. In addition to studying the development of the adaptive immune system (Pogorelyy *et al.*, 2017; Rechavi and Somech, 2017; Rechavi *et al.*, 2015) and other fundamental processes underlying the immune system in healthy individuals (Amaout *et al.*, 2011; Boyd *et al.*, 2010, 2009; Wu *et al.*, 2010b), investigation of the repertoire has the potential to reveal dysregulation in abnormal conditions such as insufficient, overly active or misdirected immune responses (von Büdingen *et al.*, 2012; Cameron *et al.*, 2009; Lehmann-Horn *et al.*, 2013; Palanichamy *et al.*, 2014; Singh *et al.*, 2013; Snir *et al.*, 2015; Stern *et al.*, 2014; Zuckerman *et al.*, 2010a), as well as infectious diseases (Laserson *et al.*, 2014; Parameswaran *et al.*, 2013; Sok *et al.*, 2013; Tsioris *et al.*, 2015), allergy (Patil *et al.*, 2015; Wu *et al.*, 2014), cancer (Fridman *et al.*, 2012; Galon *et al.*, 2006; Glanville *et al.*, 2011; Jiang *et al.*, 2015; Katoh *et al.*, 2017; Lossos *et al.*, 2000; Yahalom *et al.*, 2013), and aging (Ademokun *et al.*, 2011; Dunn-Walters and Ademokun, 2010; Dunn-Walters *et al.*, 2003; Wu *et al.*, 2012).

Fig. 1 B cell maturation. Stem cells DNA contains many potential genes for the V, D and J regions. During B cell development, one V gene, one D gene and one J gene are recombined to form the variable region of the Ig. Further diversity is added at the boundaries between the segments, by trimming and template-less addition of nucleotides. After encountering a pathogen, activated B cells undergo an affinity maturation process, resulting in mutated high-affinity Igs.

Ig repertoires are also starting to be utilized in several clinical settings including the detection of minimal residual disease in leukemia (Logan *et al.*, 2011) and analysis of tumor-infiltrating B cells for cancer prognosis (Zhang *et al.*, 2017). A snapshot of the immune system could serve as a natural bio-sensor for diagnostic and prognostic purposes. Indeed, recent studies have found that common Ig sequences can be found in unrelated individuals, for example, following Dengue (Parameswaran *et al.*, 2013) or Zika virus infection (Magnani *et al.*, 2017), in multiple sclerosis (Cameron *et al.*, 2009), and rheumatoid arthritis (Tak *et al.*, 2017), and therefore may be of diagnostic value. Repertoire analysis could also allow for diagnosis of diseases in early stages, and personalized medical treatment. Moreover, analysis of Ig repertoire sequential snapshots can teach us about the dynamics of the arms race between the immune system and the threat.

The diverse repertoire of B lymphocytes is constantly changing. Ig diversification endows the system with the ability to recognize any biological molecule or pathogen. However, the huge diversity and dynamic nature of Ig repertoires make their study challenging. Recent developments in high throughput sequencing (HTS) enable researchers to obtain large numbers of sequences from multiple samples simultaneously and increase the detection power (Ademokun *et al.*, 2011; Boyd *et al.*, 2010; Campbell *et al.*, 2008; Prabakaran *et al.*, 2012; Scheid *et al.*, 2009). Here, we describe protocols for construction Ig libraries for HTS, analysis methods, clonotype inference, i.e. classification of Igs into clones based on their V(D)J sequences, ontogeny inference, i.e. lineage trees of Ig evolution during antigen-driven affinity selection, and applications of clonotype and ontogeny inference.

Sequencing Approaches – Pros and Cons

Dramatic improvements in HTS technologies now enable large-scale characterization of Ig repertoires (Benichou *et al.*, 2012; Georgiou *et al.*, 2014). HTS platforms such as MiSeq by Illumina are being exploited by most researchers in the field (Arnaout *et al.*, 2011; Boyd *et al.*, 2010, 2009; von Büdingen *et al.*, 2012; Jiang *et al.*, 2011; Krause *et al.*, 2011; Weinstein *et al.*, 2009; Wu *et al.*, 2010b). MiSeq can generate 10 to 20 million paired-end 300 base-pair reads in a single run with relatively few errors (Loman *et al.*, 2012) and is expected to be extended to 400 base-pair reads in the near future. Other HTS platforms include Ion torrent, Pacbio, and minION (Goodwin *et al.*, 2016).

The choice of library preparation protocol involves several decisions that influence the experimental setup, the bioinformatic pipeline, and the type of information that can be extracted from the data. For example, single-cell sequencing is becoming more and more widespread in many biological applications, and is expected to spread also into Ig repertoire sequencing (Briggs *et al.*, 2017; DeKosky *et al.*, 2014). However, current technologies for Ig single cell sequencing are dramatically more expensive and complicated, and as a consequence far less popular. Other aspects that need to be taken into consideration when choosing a library preparation protocol are whether to use DNA or RNA as starting material, which sets of primers should be used, and if and how to include unique molecular identifiers. The pros and cons of choosing between DNA vs. RNA are summarized in Table 1.

UMI

A relatively recent major improvement to Ig repertoire library preparation protocols is the inclusion of unique molecular identifiers (UMIs), i.e. random sequences of 10–15 nucleotides that are added to the tail of the reverse transcription primer(s) (Jiang *et al.*, 2013; Mamedov *et al.*, 2013; Shiroguchi *et al.*, 2012; Shugay *et al.*, 2014). These barcodes tag each individual molecule with a specific barcode, so each amplicon can be traced to a consensus sequence, providing a means to distinguish real somatic mutations

Table 1 Pros and Cons for using DNA vs. RNA

	DNA	RNA
Number of molecules	(+) One DNA molecule encoding for one type of functional Ig in each cell, and thus the sequencing results reflect cell type distribution to some extent.	(–) Many RNA molecules in each cell, the number is highly variable between cells, thus the sequencing results reflect mRNA distribution which can be skewed due to Ig secreting plasmablasts.
Material stability	(+) Much more stable, enables working with difficult samples, e.g., formalin preserved.	(–) Less stable. Even if stored in -80°C , RNA can degrade after a few months.
Number of steps required for library preparation	(+) Ready for PCR.	(–) Requires an additional reverse transcription step.
Isotype information	(–) Lost, since the intron between the constant and variable regions is too large for PCR.	(+) One can use primers corresponding to the 5' edge of the constant region to obtain isotype information with minimal addition to the length of each molecule in the library.
Published protocols	(–) Few. None includes UMI, which makes PCR and sequencing error as well as bias correction impossible.	(+) Many, including UMI, so error and bias correction are possible.

from PCR amplification and sequencing-dependent errors. UMIs also help in correcting PCR amplification biases stemming from varied primer efficiencies. Although theoretically possible, no protocol for using UMIs on Ig DNAs has been published yet.

The Choice of Primer Sets

The high diversity of the Ig encoding region poses a challenge for reverse transcription or amplification during library preparation. In humans, for example, there are 9 possible constant genes for IgM, IgD, IgE, IgA1, IgA2, IgG1, IgG2, IgG3, IgG4, or 6 possible J genes, and there is no single primer that can capture all constant or J genes at the 3' end. At the 5' end, the challenge is even greater, with more than 200 possibilities for functional V alleles in the heavy chain (Lefranc *et al.*, 2009). To cover these sequences there is a need for a minimum of ~40 primers. Extension of the transcript into the 5'UTR reduces the minimum number of necessary primers to 12, still a considerable and bias-prone number for a single PCR reaction. Moreover, due to SHM, even if the Ig sequence originated from a sequence that was included in the primer set, the mutated Ig sequence, including its 5' UTR, can be very different and hence will not be amplified. A method to circumvent the need for so many primers is to perform the reverse transcription with primers only for the J or constant regions, using a 5' RACE polymerase. This polymerase incorporates a sequence of several free cytosine (C) nucleotides at the end of each newly synthesized molecule, followed by template switching with any primer that contains a sequence of 3 RNA guanine (rG) nucleotides at the 3' end. As a result, 5' RACE eliminates the potential amplification bias and can be used to amplify highly mutated sequences and sequences of species with limited information about the diversity of their Ig loci. To date, 5' RACE can only be used when the starting material is RNA.

Single Cell Sequencing

Each Ig molecule comprises two identical light chains and two identical heavy chains, linked by disulfide bonds. Most current experimental protocols sequence only the heavy chain gene, since this gene contains most of the diversity of the Ig molecule. In some cases, heavy and light chains are sequenced separately from the same sample, but high-throughput pairing of light and heavy chain sequences originating from a single lymphocyte remains a highly non-trivial challenge (Busse *et al.*, 2014; Dekosky *et al.*, 2013, 2014; Tan *et al.*, 2014; Zhu *et al.*, 2013). Currently, the best experimental approach for retaining the pairing of heavy and light chains is performing single cell barcoding (Briggs *et al.*, 2017) or linkage PCR (Dekosky *et al.*, 2013; McDaniel *et al.*, 2016) within emulsion droplets. Although promising, currently these methods are much more costly than bulk sequencing, typically resulting in a reduced number of sequenced cells per experiment. Another approach is to combinatorically identify and pair heavy and light chains based on their frequencies in the B cell repertoire (Zhu *et al.*, 2013), i.e. the most abundant VL with the most abundant VH, and so forth. However, this approach is noisy for large data sets and works well only for very abundant sequences.

Library Preparation

B cell isolation or enrichment can be performed, for example, by FACS sorting or ficoll gradient, respectively. Cells are lysed and RNA or DNA is extracted. Then the variable region of the Ig gene is amplified by reverse transcription (in the case of RNA) and PCR, using primers as described above (see "The choice of primer sets" subsection). The primers include overhanging extensions with UMIs, sample barcodes, annealing sites for the sequencing primers, and adaptors for the sequencer. Usually, two PCR steps are required, due to the length of overhang extensions on the primers, and sometimes the need to perform nested PCR to increase specificity. Another possibility to add the above extensions is by ligation. After verification of product size and quality, e.g. by tapestation or bioanalyzer analysis, the concentration is adjusted to fit the sequencer requirements, and the library is ready for sequencing (Fig. 2).

A specific problem for Ig repertoire HTS is the highly similar nature of the Ig sequences, which leads to failure of the Illumina sequencer to distinguish neighboring clusters. This can be alleviated by spiking the desired library with a control phiX virus library, and/or replacing each primer with a mixture of 4 primers, where the body of the primer is identical except for 0–3 extra random nucleotides that are added at the beginning of it.

Ig Repertoire Sequence Data Pre-Processing, Annotation and Clonal Assignment

The theoretical diversity of Igs is immense. Igs are combined of a light and a heavy chain, of varying lengths. For example, a typical heavy chain is between 330 and 390 base pairs, so naively, one could think that there are $4^{330-390}$ possible combinations for this sequence. Structural constraints reduce this number dramatically, but still the estimated diversity of the heavy chain only is $\sim 10^9$ (Murphy and Weaver, 2016).

Pre-Processing

Many non-Ig HTS applications assume that the sequenced amplicons can be mapped and compared to a reference genome (Michaeli *et al.*, 2012). Due to the somatic rearrangement discussed above, a B cell clone creates its unique Ig sequence, with no

Fig. 2 The process of Ig repertoire sequencing and analysis. Starting from either RNA (top right) or DNA (top left), the variable region of the Ig gene is enriched and amplified, and adaptors are added for HTS. The raw sequencing reads undergo preprocessing to filter out irrelevant and low-quality sequences, and the high-fidelity reads are aligned to the known reference genes, annotated and clonotyped, followed by lineage tree construction.

complete reference in the genome, and further diversifies it through SHM. Thus, tailored tools for preprocessing Ig repertoires sequencing data had to be developed by the computational immunology community (see, e.g., Georgiou *et al.*, 2014; Vander Heiden *et al.*, 2014; Michaeli *et al.*, 2012, 2013; Moorhouse *et al.*, 2014; Schaller *et al.*, 2015; Wardemann and Busse, 2017; Yaari and Kleinstei, 2015). First, Ig repertoire sequencing data require a large amount of pre-processing work to clean out the data and prepare them for more specific downstream analysis related to clonal identification and mutation analysis. Specific computational toolkits tailored for Ig repertoires sequencing purposes perform pre-processing of raw sequencing reads and produce error-corrected, sorted and annotated sequence sets, along with a wealth of quality control metrics (Bolotin *et al.*, 2015; Vander Heiden *et al.*, 2014; Michaeli *et al.*, 2012). These tools include, for example: a. Removal of low-quality reads. b. Removal of reads

where the primer could not be identified or had a poor alignment score. c. Identification of sets of sequences with identical UMIs. These are collapsed into one consensus sequence per set. d. Assembly of the two consensus paired-end reads into a complete Ig sequence. e. Removal of sequences that do not appear in a single sample with at least two independent molecular IDs (see also Stern *et al.*, 2014).

Annotation

Ig repertoire analysis benefits from adequate annotations. For example, each Ig sequence is derived from a combination of V, D, and J germline genes, which could be inferred from the Ig sequence using different tools (Bolotin *et al.*, 2015; Brochet *et al.*, 2008; Gaëta *et al.*, 2007; Munshaw and Kepler, 2010; Ralph and Matsen, 2016; Ye *et al.*, 2013). These VDJ assignment tools return for each Ig an aligned germline sequence, constructed from the inferred V, D, and J genes, taking into account the possibilities for trimming the edges of these genes and inserting alien nucleotides in between them (N and P additions) ((Murphy and Weaver, 2016), Fig. 1). Germline sequence annotations reduce the dimensionality of the sequence space, and enable a more comprehensible and interpretable analysis. Furthermore, and most importantly, somatic mutations can be identified from the germline sequence, and be used for phylogenetic tree construction, selection quantification, and building somatic mutation models. To identify the V and J genes, methods based on sequence similarity are commonly used (Lefranc *et al.*, 2009; Ye *et al.*, 2013). The inference of the D gene and its flanking sequences is a more difficult task, due to the stochastic processes underlying VDJ recombination and the relatively short lengths of the D genes. Several statistical frameworks to cope with this stochastic process exist, including HMM (Gaëta *et al.*, 2007; Munshaw and Kepler, 2010) and an E-M iterative process that first estimates the probabilities for each event from the whole dataset, and then aligns the sequence to the inferred germline (Marcou *et al.*, 2017).

Germline Repertoire Inference

Another important point in VDJ assignment is the ability to a priori set the V, D, and J, germline repertoires. Studying polymorphisms in the Ig loci in human populations is an active field. Recent studies suggest that there are complex events of deletion and duplication in these loci, yielding an undiscovered wealth of unknown alleles (Kidd *et al.*, 2012; Luo *et al.*, 2016; Wang *et al.*, 2008; Watson and Breden, 2012; Watson *et al.*, 2013). IMGT has a central repository for V, D, and J allele sequences; to add new sequences to this repertoire there is a need for direct DNA sequencing of non B cells. In recent years, several independent methods to detect novel polymorphisms from Ig repertoires have been developed (Corcoran *et al.*, 2016; Gadala-Maria *et al.*, 2015), and there is an ongoing effort to define a set of rules that will allow recognition by the community of these inferred alleles (Brenden *et al.*, 2017). Comparing Ig sequences to all known alleles can result in erroneous gene assignments, because alleles might be missing in current germline gene datasets, and since highly mutated sequences may be mis-assigned. To reduce this risk, a genotype and/or a haplotype step that generates a personalized pool of possible alleles can be performed. In a genotype step, all sampled sequences from an individual are combined, and a decision is made about the set of alleles that the individual actually has. After creating such a genotype, VDJ assignment is repeated with the restricted set of available germline genes. Such a step can reduce the number of mis-assigned sequences dramatically (Gadala-Maria *et al.*, 2015). To haplotype a repertoire, one can use J (or D) gene heterozygosity and analyze the frequency of recombined J (or D) alleles with V alleles (Kidd *et al.*, 2012). After inferring a haplotype for an individual, VDJ assignment should be repeated to ensure that alleles are co-assigned to a sequence only if they are present on the same chromosome. After the VDJ assignment step, each sequence is annotated with its inferred germline genes, trimmed and added sequences, CDR3 length, charge, etc.

Clonal Assignment

One of the leading themes behind our understanding of adaptive immunity is clonal selection, and the idea that T and B cell repertoires are comprised of groups of cells of varying sizes, each of which derived from a common ancestor (Hodgkin *et al.*, 2007). While in T cells it is straightforward to identify these clonally-related sequences, as they are identical in all the cells belonging to the same clone, in B cells, due to SHM, inferring these groups from Ig repertoire sequencing data is a statistically non-trivial task (Chen *et al.*, 2010; Hershberg and Luning Prak, 2015). Since the number of sequences in a typical Ig repertoire sequencing experiment is in the order of millions, clustering these sequences requires tailored approaches from machine learning and statistics. Clones are usually inferred based on their heavy chain sequences, as light chain diversity alone is too low for this task (Saada *et al.*, 2007). When heavy and light chain sequences are paired (Dekosky *et al.*, 2013, 2014), the combined information can be used for clonal assignment.

Clonal assignment is normally performed in two steps. First, sequences are grouped based on their V-J gene calls and junction length annotations. Second, a sequence-based distance measure is used to cluster the sequences inside each group. Due to the nature of SHM, the common distance metric is based on nucleotide similarity, and in most cases is applied to the CDR3 part of the sequence. In principle, it is possible to cluster the sequences based on sequence similarity throughout the whole variable region, and also allow for insertions and deletions that can occur during SHM (Kepler *et al.*, 2014a). However, in most studies these are not considered. It is also possible to use a distance metric that is based on a mutability model that takes into account hot and cold spots of SHM (Elhanati *et al.*, 2015; Yaari *et al.*, 2013).

After constructing a distance matrix, clustering can be performed using approaches such as imposing a threshold on a hierarchical tree using either single, complete or average linkage. To determine the adequate threshold, a “distance-to-nearest” plot (Glanville *et al.*, 2011) can be utilized. Since biological clones are restricted to a single individual, inferred clones that span multiple individuals can be used to estimate specificity for clonal assignment. With these assumptions, it was shown that “hamming distance” using single linkage clustering performs better in terms of specificity and sensitivity (Gupta *et al.*, 2015; Yermanos *et al.*, 2017). Alternatives to the distance matrix clustering include cutting lineage trees (see below) to create subtrees that can be interpreted as clones (Lieberman *et al.*, 2013), and maximum likelihood approaches (Kepler *et al.*, 2014a; Wu *et al.*, 2011). Initial V(D)J assignments can be refined after clonal assignments as all sequences stemmed from the same cell have the same germline (Kepler, 2013; Stern *et al.*, 2014). Although V(D)J assignments are not required for clonal assignment (Giraud *et al.*, 2014), utilizing these annotations makes it possible to cluster much larger data sets with standard clustering methods.

Grouping similar sequences can also serve other purposes. Similar receptor sequences could indicate similarity in function. For example, the similarity of TCRs was recently shown to help in predicting epitopes (Dash *et al.*, 2017; Glanville *et al.*, 2017). Functionally similar Ig sequences across individuals indicate “public” immune responses (Glanville *et al.*, 2011). These sequences can also indicate convergent evolution where multiple clones produce independently similar Ig sequences at the amino acid level, but not necessarily using the same genes (Jackson *et al.*, 2014; Parameswaran *et al.*, 2013). For these applications, sequence similarity at the amino acid level can be used for clustering.

Repertoire Analyses

Common Repertoire Measures and Coping With Inherent Biases

Ig repertoires are characterized by many features that allow researchers to reduce their high dimensionality and describe them in biologically meaningful terms. Examples include: V-D-J gene usage distribution, isotype usage distribution, various measures of repertoire diversity and similarity, CDR3 length distribution, amino acid composition, and mutation patterns. The interpretation of these distributions and measures depends on various factors, such as the sequenced material (mRNA or DNA), whether a UMI approach was taken, and whether bulk or single cell sequencing was done (see Table 1). For example, amplification biases can dramatically influence the results if each sequence is counted independently and UMIs are not utilized. Even if UMIs are utilized, the measured distribution will describe the mRNA distribution, which can be very misleading as some cells (plasmablasts) have orders of magnitude higher numbers of mRNA molecules than B cells. A common way to confront these biases is to construct the distributions from the set of unique sequences. However, this approach still cannot overcome the experimental artifacts, such as transcription and amplification errors. Yet, a repetitive important task in Ig repertoire analysis is to calculate the above feature distributions and conclude from them something about repertoire generation and dynamics. For example, using the D-J genes distribution to infer the inherent constraints and preferences of the V-D-J recombination machinery. To do this, researchers commonly pick one sequence from every clone and compute the distributions from these representatives. On the other hand, taking only one representative from every clone leaves most of the data unanalyzed. To exploit more information from the data, it is necessary to also integrate the construction of lineage trees into the analysis, as discussed below.

In a healthy repertoire, large clones are rare, and we usually sample only one or a few cells per clone (Hershberg and Luning Prak, 2015). Even during an acute infection, only a few responding clones grow and may constitute at most a few percent of the repertoire. In contrast, if the clonal size distribution contains one or more highly frequent clones, we may suspect the presence of an autoimmune disease such as Sjogren’s syndrome (Hershberg *et al.*, 2014) systemic lupus erythematosus following rituximab therapy (Sfikakis *et al.*, 2009), or a B cell malignancy such as chronic lymphocytic leukemia (Logan *et al.*, 2011). Positive selection for independent B cell clones often results in shared amino acid sequence motifs that bind to particular antigens. Such public CDR3 motifs have been documented in many chronic disorders ranging from viral (Jackson *et al.*, 2014; Wrammert *et al.*, 2011) or bacterial (Scott *et al.*, 1989; Silverman and Lucas, 1991) infections and autoimmunity to cancer.

Repertoire Diversity

Repertoires may differ from one another in many ways. Quantifying these differences is a research field of its own, and includes many possibilities to assess diversity and similarity of repertoires. One potent approach to measure diversity is the Hill diversity index (Hill, 1973). This index can be applied to any feature distribution (e.g. V gene usage), and usually is applied to characterize the clone size distribution. It is defined as

$$qD = \left(\sum_{i=1}^{i=n} p_i^q \right)^{(1/(1-q))}$$

where the sum is over all clones and p_i is the fraction of clone i out of the entire population. This diversity index converges to all of the known diversity measurements for different values of the parameter q . For example, for $q = 0$, D is the number of species (a.k.a. richness); for $q = \infty$, D is the reciprocal of the fraction of the largest clone; for $q = -\infty$, D is the reciprocal of the fraction of the smallest clone; for $q = 1$, D is the exponent of Shannon’s entropy, and higher values of q (2, 3 etc.) give a higher weight to the larger clones. Studying the shape of this curve is much more informative than measuring a single diversity score along with an

“evenness” score (Hill, 1973). When comparing diversity profiles between samples, it is advised to subsample (with replacement) the larger repertoire to the size of the smaller one and only then to compare the two (Gupta *et al.*, 2015).

Lineage Tree Analysis & Lessons Learned From Tree Structure

During affinity maturation, Ig loci accumulate mutations via SHM. An important step in Ig repertoire analysis is the inference of each clone’s pedigree. These pedigrees are referred to as lineage trees, and methods to infer them are usually borrowed from the field of phylogeny, despite different assumptions underlying each case. For example, in B cell lineages, the trees are rooted by the rearranged, pre-mutation sequence. This sequence is not necessarily the most recent common ancestor of the tree, but is used to construct the tree.

Lineage Tree Construction

The phylogenetic methods most commonly used for analysis of Ig repertoire sequencing data are maximum likelihood, maximum parsimony, neighbor joining (Barak *et al.*, 2008) and Bayesian inference (Yermanos *et al.*, 2017). These methods utilize a distance metric to construct the trees. The most common distance metrics are the Hamming, Kimura substitution model (Kimura, 1968), and Levenshtein distances. Since SHM preferences are based on neighboring nucleotides, a more adequate distance metric should take into account these neighboring nucleotides. A first step to integrate neighboring bases effects in constructing a B cell lineage tree was taken recently (Hoehn *et al.*, 2017). It was evaluated using trees constructed from HIV patients (Wu *et al.*, 2015), and showed better performance. A method based on natural SHM metrics, such as the S5F (Yaari *et al.*, 2013) or 7mers (Elhanati *et al.*, 2015) is still lacking. Given a distance metric, the differences in performance between the methods are mild (Yermanos *et al.*, 2017). In order to use the outputs of lineage tree construction algorithms, there is a need in parsing the resulting trees and fit them to Ig repertoires (Barak *et al.*, 2008; Vander Heiden *et al.*, 2015), as most phylogenetic algorithms assume that all observed sequences are at the leaves of the tree. Also, in B cell lineages the germline sequence should be upstream of the root of the tree.

Lessons Learned From Lineage Trees

Merely constructing Ig lineage trees sheds light on fundamental processes underlying the immune system in health and disease, and may aid in vaccine and drug design. We present here a few examples, which are by no means an exhaustive set. Tabibian-Keissar *et al.* (Tabibian-Keissar *et al.*, 2008) used lineage trees to give the first direct evidence of trafficking between human colon and adjacent lymph nodes, Bergqvist *et al.* (Bergqvist *et al.*, 2013) used trees to show the spreading and synchronization of IgA responses throughout the murine gut, and Pabst *et al.* (Pabst *et al.*, 2015) used trees of sequences from serial mouse gut biopsy samples to show the development of the murine gut immune system. Hazanov *et al.* (Hazanov *et al.*, 2015) have used lineage tree structures to elucidate the relationships between switched memory, IgM memory, naïve and IgD-CD27 – (double-negative, “DN”) B cells in humans. Meng *et al.* (Meng *et al.*, 2017), with the aim of enhancing our understanding of the distribution of B cell clones in the human body, sequenced and analyzed over 38 million B cells from eight anatomic compartments. They found two major networks of large clones, one in the blood, bone marrow, spleen and lung, and another in the GI tract, with little overlap between the networks. The GI tract contained large clones with the highest levels of somatic hypermutation.

SHM and class switching

Horns *et al.* (Horns *et al.*, 2016) developed a way to reconstruct the B cell proliferation process and thereby trace the lineage of individual B cells, using somatic hypermutations as a molecular clock. They revealed that closely related B cells often switch to the same class, but lose coherence as somatic mutations accumulate. They also found that naïve classes (IgM or IgD) accumulated more mutations before undergoing class switch recombination to activated classes (IgG, IgA, or IgE), in comparison with class switch recombination between activated classes. These findings lay a foundation for developing techniques to direct Ig class switching. Kepler *et al.* (Kepler *et al.*, 2014b) analyzed paired heavy-light lineage trees of an influenza-infected individual, and showed how affinity maturation occurs stepwise with time within clones, increasing 1000-fold from the unmutated ancestor to the highest affinity observed Igs.

Aging

Jiang *et al.* (Jiang *et al.*, 2013) and the Dunn-Walters lab (Ademokun *et al.*, 2011; Tabibian-Keissar *et al.*, 2016; Wu *et al.*, 2012) determined the lineage structure of the Ig repertoire before and after influenza vaccination, and observed age related changes. Elderly subjects had fewer lineages than other age groups, both before and after vaccination, and influenza vaccination resulted in expansion of far fewer B cell lineages and a reduced B cell clonal diversity in the elderly compared to the younger age groups. The elderly had a higher percentage of somatic mutations, likely since their clonal expansions draw upon a pool of B cells having more somatic mutations to begin with.

Infection and response dynamics

Highly effective, broadly neutralizing Igs towards HIV have unusual characteristics (Burton *et al.*, 1994; Calarese *et al.*, 2003; Haynes *et al.*, 2005; Huang *et al.*, 2004; Klein *et al.*, 2013; Pancera *et al.*, 2010; Pejchal *et al.*, 2010; Scheid *et al.*, 2011; Walker *et al.*,

2009, 2011; Wu *et al.*, 2010a, 2011; Zhou *et al.*, 2007) and usually take years of chronic infection to develop (Gray *et al.*, 2011; Wu *et al.*, 2006). The best studied broadly neutralizing Ig lineages are VRC01, VRC26, and CH103 (Doria-Rose *et al.*, 2014; Liao *et al.*, 2013; Wu *et al.*, 2015). Wu *et al.* (Wu *et al.*, 2015) investigated VRC01, which targets gp120, the site of CD4 engagement on HIV-1. They identified and described Ig lineage characteristics over the course of 15 years in a single patient. Most Igs differ from the germline by ~5%, but the VRC01 lineage is over 30% different. Over the course of the study, the authors showed using lineage trees that VRC01 Igs continuously evolved, with a rate of ~2 substitutions per 100 nucleotides per year, comparable to that of HIV-1 evolution. Liao *et al.* (Liao *et al.*, 2013) followed the CH103 Ig lineage, also targeting gp120, in a single donor over 3 years. They showed the evolution of the lineage up to a mature broadly neutralizing Ig that could neutralize ~55% of HIV-1 isolates. This lineage is less mutated than other CD4-binding Igs, and may be first detectable as early as 14 weeks after infection. Therefore, the CD4-binding site may be a vaccine target. Doria-Rose *et al.* (Doria-Rose *et al.*, 2014) delineated longitudinal interactions between the development of 12 related broadly neutralizing Igs and HIV-1 within a single donor over 4 years. They found that the unmutated ancestor of the lineage emerged between weeks 30–38 post-infection, bound and neutralized the virus weakly and did not bind any other HIV strains. Later variants demonstrated increasing affinity towards several strains of the virus. Subsequent affinity maturation focused within CDR H3 and allowed for progressively greater binding and neutralization. This work defined the molecular requirements and genetic pathways leading to virus neutralization, providing a template for their vaccine elicitation. Sok *et al.* (Sok *et al.*, 2013) developed a novel method called ImmuniTree, which is an alternative approach to conventional phylogenetic analyses and is designed specifically to model Ig somatic hypermutations. They used this method to study the PGT121-134 broadly neutralizing Ig lineage, which is also characterized by high levels of somatic mutations and is among the most potent lineages described to date. They discovered Igs in the lineage with half the mutation level of PGT121-134, capable of neutralizing 40%–80% of PGT121-134 sensitive viruses. Such Igs will likely be easier to induce through vaccination.

Autoimmune diseases

Autoimmune responses also generate large clones, and various insights can be gleaned from analysis of the corresponding lineage trees. Stern *et al.* (Stern *et al.*, 2014) and Palanichamy *et al.* (Palanichamy *et al.*, 2014) analyzed B cell repertoires from the brain and lymph nodes of multiple sclerosis patients, and showed that B cells populating the multiple sclerosis brain mature in the draining cervical lymph nodes, and that the traffic between the periphery and the brain is an ongoing process, and not a one-time event as was previously thought. This provides insight into the trafficking of B cells in MS. Therefore, modulation of specific B cell subsets could provide therapeutic benefit in MS patients. Snir *et al.* (Di Niro *et al.*, 2016; Snir *et al.*, 2015) compared B cell clones in the gut and blood of celiac patients, and found that the generation of plasma cells producing autoantibodies likely occurs outside the gut. Such knowledge helps to shed light on the molecular mechanisms causing the disease, and may facilitate the development of immune-based therapies.

Mutation Analyses Relying on Lineage Tree Structure

Lineage tree graphical properties can be used by themselves to estimate the relative strength of selection, mutation and initial competitive advantage of clones (Shahaf *et al.*, 2008), and thus to characterize a specific immune response. However, the most useful feature of the trees is the mutations they are constructed from. Analyzing mutation patterns in Ig repertoires can shed light on the underlying biology of B cell adaptation, and can be used to estimate affinity dependent selection. For any analysis of mutation patterns, reliable lineage trees should be used to identify independent events of mutations. If one ignores the lineage structure of a B cell clone, mutations can be counted multiple times as an artificially larger number of independent events. This may lead to severe biases in mutation analyses. Integrating lineage tree structure in the analysis should thus be used to count each mutation event only once. In addition, tree structure enables more correct identification of each mutation (as each sequence is compared to its most recent identifiable ancestor, and not to the root), and the identification of reversion mutations.

The patterns of mutations carry the fingerprints of the SHM machinery – from AID targeting sites (Chandra *et al.*, 2015) to the various pathways to deamination site resolution (Zanotti and Gearhart, 2016). In most of our studies, whether the focus was aging, chronic or autoimmune diseases or B cell malignancies, we have found no differences from controls in mutation statistics such as targeting motifs, transition: transversion ratios, the fraction of mutations from and to each nucleotide, etc. A noteworthy exception was seen in studying ectopic GC from myasthenia gravis patient thymi. Using tree-based mutation analysis, Zuckerman *et al.* have predicted changes in the SHM mechanism (Zuckerman *et al.*, 2010b), a prediction which was verified by gene expression analysis.

Selection analysis has many applications, including identification of potentially high affinity sequences, understanding how different genetic manipulations impact affinity maturation, and investigating whether disease processes are antigen-driven. It is common to look for an increased frequency of non-synonymous mutations as evidence of antigen-driven positive selection, and a decreased frequency of non-synonymous mutations as evidence of negative selection (Hershberg *et al.*, 2008; Uduman *et al.*, 2011; Yaari *et al.*, 2012). Expectations are calculated either using a uniform targeting model in which all mutations occur with the same rate (Lossos *et al.*, 2000; Shlomchik *et al.*, 1987), or using a mutability model such as the S5F (Yaari *et al.*, 2013).

When quantifying selection in Ig sequences, mutations can be calculated in several time scales. An Ig sequence can be compared to the germline sequence, to the most recent common ancestor, or to the sequence that is one branch upstream in the tree. These different comparisons yield different selection estimations. Lineage trees were used to show how selection is stronger along the tree

vs. close to its leaves (Uduman *et al.*, 2014). It was also shown that memory cells from past infections experienced stronger selection compared to current clonal expansion (Yaari *et al.*, 2015).

Summary and Challenges for the Future

The analysis of TCR and BCR clonal repertoires differs from other bioinformatic practices due to the lack of reference genes, and with the amounts of data generated by HTS, is more complex. On the other hand, as shown by the examples shown above, it has an enormous potential for generating new insights into the structure and activity of the immune system at every stage of life and when faced with any challenge. We eagerly anticipate the day in which knowing a person's BCR and TCR "haplotypes" and having a good sample of their repertoire would give us as much knowledge of their immune status as the rest of their genome can tell about their health status and potential.

Before we reach that day, however, there are several challenges to overcome. First, we do not have a full understanding of the structure and contents of human BCR and TCR genomic loci; better knowledge of these genomic regions, in particular the identification of larger numbers of alleles, will accumulate as the repertoires from more and varied population groups are sequenced. Second, for sequencing of such magnitude to be possible, we need ways to generate longer, more reliable reads at far lower cost. Third, in order to understand the function of the BCRs and TCRs sequenced, we need a reliable, easy and low-cost protocol for sequencing paired heavy and light chains or beta and alpha chains. While emulsion-based methods are much less work-intensive and have higher throughputs than well plate-based methods, paired sequencing is still basically a single-cell method of analysis and hence its current output is not as high as single-chain sequencing. Fourth, in order to compare and evaluate studies and enable meta-analysis, we must standardize protocols and data format between labs. Research in the field will be facilitated by data and protocol sharing and adherence to meticulous standards (see Relevant Website Section). Finally, we should devote considerable efforts to the continued invention of new and creative ways to look at the data collected. We need ways to obtain a deeper view of the true repertoire, as even the new methods only sample a small portion of it.

Introduction

Immunology covers many areas of research, such as the production mechanisms of diverse antibodies, the formulation and maintenance of the T-cell repertoire, the development and maturation of lymphocytes, discrimination of self and non-self, and the interactions between immune cells and viruses or cancer cells (Fig. 1). By investigating these topics from both basic and clinical viewpoints, we can understand pathology and develop treatment modalities for allergies, autoimmune diseases and immunodeficiency (Kishimoto, 2005). The broad-ranging topics in immunology are underpinned by the fundamental processes of immune systems, which dictate how cells, antibodies, and pathogens interact and the consequent effects of these interactions (Kitano, 2002). Owing to recently developed experimental techniques, we can clearly visualize the immune response process and its associated changes of signal transductions and gene expressions (Orkin and Zon, 2008; Notta *et al.*, 2016; Gewirtz *et al.*, 2001; Fehniger *et al.*, 1999). Immunologists can also exploit the large body of accumulated datasets. For example, bioinformatics and statistics have revealed several parts of homeostatic mechanisms in living bodies (Martinez *et al.*, 2006). To apply the knowledge obtained from cell or animal experiments at the clinical stage (e.g., in drug development and drug treatment strategies), we must quantitatively understand immune system dynamics such as antibody production changes and cell cycling (Perelson, 2002; Perelson and Nelson, 1999; Koizumi *et al.*, 2017). Mathematical models have become increasingly popular in experimental and clinical data analysis, and are now regarded as cutting-edge tools for quantitative interpretation in immunology (Perelson and Nelson, 1999; Perelson, 2002; Michor *et al.*, 2005; Bernitz *et al.*, 2016; De Boer and Perelson, 2013). In this paper, we introduce and discuss several important data analysis studies that quantify immune-cell differentiation, lymphocyte homeostasis, and viral infection using mathematical models.

Fundamentals

In response to potentially harmful internal and external stimuli, the immune system initiates many interactions of cells, antigens, antibodies and/or cytokines. These mechanisms can be described by “population dynamics” models (Hirsch *et al.*, 2012), which temporally evolve the concentration of cells, antigens, antibodies or cytokines throughout their interactions (Efimie *et al.*, 2011). In general, cell populations undergo four processes: “birth”, “death”, “immigration” and “emigration”. In populations of immune cells, these four processes correspond to cell proliferation, death, differentiation from other populations, and differentiation into other populations, respectively (see Fig. 1). These processes are generally formulated as follows:

$$dN_i(t)/dt = (p_i - a_i - (\sum_{j=1, j \neq i}^m d_{ij})N_i(t) + (\sum_{j=1, j \neq i}^m h_{ji})N_j(t) \quad (1)$$

where $N_i(t)$ is the number of cells in population i ($i=1, 2, \dots, m$) at time t . The parameters p_i and a_i are the proliferation and death rates of cell population i , respectively, d_{ij} is the emigration rate from population i to population j , and h_{ji} is the immigration rate from population j to population i . If cells in population i migrate into population j by differentiation, then d_{ij} and h_{ji} are equal. If cells of population i are produced from cells in population j , d_{ij} is 0 and h_{ji} is positive. The coefficients might be constants or functions of $N_h(t)$ ($h=1, 2, \dots, m$) to describe interactions with other populations. This generalized model can be tailored to

Fig. 1 Schematic of the immune system. Immune cells are derived from HSCs and the immune system is homeostatically maintained in a healthy state that protects against pathogens. Homeostasis is considered to fail in the disease state. The arrows correspond to interactions between populations of cells or antigens. The interactions among populations can be incorporated into mathematical models of dynamic population changes.

model the interactions and differentiation mechanisms of cell populations of interest to the researcher. It can also include hypothetical but experimentally testable interactions. Moreover, using statistical criteria such as Akaike's Information Criterion (AIC) and the likelihood ratio test, we can select the most suitable model among several hypothetical models, discussing empirical possibilities and guiding the next steps in experimental studies (Akaike, 1974). The generalized model can clearly define the focal areas of a study, enhancing our understanding of immune systems rather more than complex models. The following sections exemplify some of the novel insights gained from the generalized model.

Applications

Owing to recent technological developments, the snapshot comparisons in classical researches can be supplemented by novel researches that quantitatively characterize biological behaviors from the dynamical changes in time-course data. In the immunology field, mathematical modeling is increasingly used for describing and quantifying the time-course data of clinical practices and animal/cell experiments.

Cell Differentiation

Cell differentiation is the process by which dividing cells change their functional or phenotypical type. All cells presumably derive from stem cells and obtain their functions as they mature. Cellular composition is often modeled as a hierarchical scheme with stem cells at the top of the hierarchy. Mathematical models of cell differentiation consider the proliferation, death, and differentiation of an appropriately distinguished cell population.

For instance, the cells in a stem cell population differentiate into multiple cells but maintain their number by self-renewal. A progenitor cell population derives from stem cells and differentiates into a restricted lineage, whereas a matured cell population derives from progenitor cells, performs some functions, and dies a natural death. Considering these populations as cell differentiation, Michor *et al.* (2005) proposed a set of ordinary differential equations (ODEs) describing the population dynamics of four cell populations (hematopoietic stem cells, progenitors, differentiated cells and terminally differentiated cells), which explains the clinical data of leukemia. In successful cancer therapy, the number of leukemic cells exhibits a biphasic exponential decline. By fitting the model to the clinical data, the authors revealed that this behavior corresponds to the turnover rates of differentiated and progenitor cells. Furthermore, their study implied that cancer therapy strongly inhibits the production of differentiated leukemic cells, but does not deplete leukemic stem cells (Michor *et al.*, 2005). Their mathematical modeling provided valuable quantitative insights.

Abundant datasets are also available for hematopoietic cell systems, for which the cell hierarchy is well characterized (Orkin and Zon, 2008; Dingli *et al.*, 2007). In hematopoietic stem cell research, the number of divisions of stem cells can be measured by labeling techniques. Bernitz *et al.* (2016) distinguished the numbers of different hematopoietic stem cells by the numbers of cell divisions, which were determined from the intensities of fluorescent protein incorporated in the stem cells. Fitting a mathematical model to the data, they estimated the rate at which the hematopoietic stem cells leaned toward a myeloid lineage during differentiation. Thus, the mathematical modeling of cell differentiation quantifies the parameters that cannot be obtained from conventional experimental data.

Lymphoid Cell Turnover

Humans maintain a stable internal environment by special mechanisms called homeostatic mechanisms, which maintain the number of cells in the body within a certain range. Consequently, the number of human lymphocytes such as T lymphocytes is usually unchanged. Dysregulation of homeostasis leads to disease conditions. Abnormal cells that increase their numbers by uncontrolled cell division become malignant cancer cells. Immune cells can become depleted or malfunctioning (leading to immune deficiency) or unusually activated to attack the body's own tissues (causing autoimmune diseases). Such disease states cannot be understood by merely comparing the numbers of cells in healthy and diseased states.

An analog of pyrimidine, 5-Bromo-2'-deoxyuridine (BrdU), can be incorporated into DNA during cell division. Under BrdU administration, dividing cells become labeled and can be detected by a BrdU antibody for measuring the dynamics of lymphocytes (Grazner, 1982). Since the 2000s, immunology studies have combined classical BrdU labeling with mathematical modeling (De Boer and Perelson, 2013). Interestingly, BrdU labeling and mathematical modeling can together quantify the proliferation or death rates of cells, and detect differences in the BrdU-labeled lymphocyte dynamics. For example, Mohri *et al.* (1998) compared the time-course BrdU labeling data from rhesus macaques infected with simian immunodeficiency virus (SIV) and their non-infected counterparts. They found that SIV infection dramatically increases the turnover of T lymphocytes. Their assumption – a constant total number of T lymphocytes – was relaxed in a later mathematical model (Bonhoeffer *et al.*, 2000). Similar approaches have quantified the turnovers of other lymphocyte populations such as B cells, T cells, and NK cells (De Boer *et al.*, 2003b). De Boer *et al.* (2003a) proposed a new index, the "average turnover rate", defined as the cellular death rate averaged over all subpopulations in the model (i.e., $\hat{\delta} = (\Sigma)_i^m (\alpha_i \delta_i)$ ($i=1, \dots, m$), where $\hat{\delta}$, δ_i and α_i are the average death rate, a death rate of subpopulation i and a fraction of subpopulation i among whole cell population, respectively, and m is the number of subpopulations.). This value is estimated similarly by different models. In summary, mathematical modeling complements conventional BrdU labeling experiments to enhance our quantitative understanding of lymphocyte dynamics.

Virus Dynamics

The representative virus of immunology studies is human immunodeficiency virus type I (HIV-1), which causes acquired immune deficiency syndrome (AIDS). Viral infection behaviors, called “virus dynamics”, have been mathematically studied since the 1990s (Ho *et al.*, 1995; Wei *et al.*, 1995). Mathematical models of virus dynamics have analyzed many kinds of *in vivo* experimental and clinical data, and have elucidated various aspects of HIV biology, especially, the average lifespan of virus-producing cells (Simon and Ho, 2003; Perelson, 2002). Many recent studies have combined mathematical modeling with cell culture (i.e., *in vitro*) experiments (Beauchemin *et al.*, 2017; Ito *et al.*, 2017; Iwami *et al.*, 2015; Iwanami *et al.*, 2017; Mahgoub *et al.*, 2018; Ikeda *et al.*, 2015). In cell culture experiments, one can measure several different kinds of time-course experimental data, enabling robust parameter estimation for the mathematical model. For example, Ikeda *et al.* (2015) coupled mathematical modeling with cell culture experiments to quantify the antiviral effects of interferon (IFN) on HIV-1 infection. They deduced that IFN acts by inhibiting *de novo* infection rather than virus production. Thus, quantitative estimates can help to resolve unanswered questions in immunology.

Analysis and Assessment

Mathematical Modeling of Hematopoietic Stem Cell Differentiation

The type and number of the target cells can be measured in flow cytometers. The functional types of immune cells are easily distinguished by markers attached on the cells. Therefore, the differentiation rates or pathways can be theoretically estimated by analyzing the count data of cell phenotypes in mathematical models. In simple terms, differentiation occurs when either or both of the two daughter cells change(s) after cell division. To mathematically describe cell differentiation, we set the number of daughter cells as twice the number of mother cells, then immigrate some of the daughters into the next cell population at a certain rate, maintaining the others in their current precursor population. For example, Thomas-Vaslin *et al.* (2008) described the differentiation process from CD4 and CD8 double-negative T lymphocytes in the thymus to CD4 or CD8 single-positive naïve T lymphocytes in the spleen by ODEs. Fitting their mathematical model to the measured number of T lymphocytes in each cell-differentiation stage, they estimated the turnover rate of each stage and the death rate of T lymphocytes in the thymus. Schlub *et al.* (2009) theoretically explained the formulation mechanism of central- memory and effector-memory T lymphocyte repertoires. Here, the memory cells compose the immunological memory. Buchholz *et al.* (2013) mathematically identified conceivable differentiation models (from naïve T cells to central memory precursors, effector memory precursors, or effector cells) by fitting them to time-course data. The best-fit model was selected by ranking the AICs of the models. These studies are expected to elucidate the homeostasis mechanism of the immune system against various stimuli.

For a deeper understanding of immune-system homeostasis, we need to elucidate the differentiation of hematopoietic stem cells (HSCs), which sustain the production of immune cells. Although HSCs are known to differentiate into two major lineages (the lymphoid and myeloid lineages), how these lineages branch during HSC differentiation and how aging HSCs maintain their homeostasis and functions are not fully understood. In fact, diseases related to the immune system are sometimes considered to arise from disorders of aging HSCs. Crude markers and functional heterogeneity of HSCs have been reported (Yamamoto *et al.*, 2013). Therefore, by combining mathematical modeling with flow-cytometer measurements of HSC numbers, we might elucidate the mechanism of HSC differentiation. HSC differentiation is among the most fundamental processes in immune-cell differentiation, and HSC research has recently adopted mathematical modeling for quantitatively understanding the differentiation phenomena. Assuming that HSCs expand through four symmetric divisions, the increasing HSC numbers during aging can be described by the following ODEs (Fig. 2):

$$\begin{aligned}
 dx_0(t)/dt &= -k_0x_0(t) \\
 dx_1(t)/dt &= 2k_0x_0(t) - k_1x_1(t) \\
 dx_2(t)/dt &= 2k_1x_1(t) - k_2x_2(t) \\
 dx_3(t)/dt &= 2k_2x_2(t) - k_3x_3(t) \\
 dx_4(t)/dt &= 2k_3x_3(t) - k_4x_4(t)
 \end{aligned} \tag{2}$$

Here, $x_n(t)$ is the number of HSCs that have divided n times ($n=0, 1, 2, 3, 4$) and $1/k_n$ is the expected time interval to the next division for a cell that has previously divided n times. After fitting the model to the measured number of HSCs in young mice, the division rate of murine HSCs that had divided n times was best described by $k_n = k\beta^{2n}$ ($0 < \beta < 1$) (Bernitz *et al.*, 2016). Note that by using phenotypes (which roughly distinguish HSCs from other cells), and by tracking the intensity of fluorescent protein (which decreases by half after each cell division), we can measure the number of cells corresponding to each of the n division events.

As HSCs age, their differentiation ability leans toward the myeloid lineage (Notta *et al.*, 2016), and the fraction of cells expressing CD41 (a marker of increased myeloid differentiation) is lower in young mice than in adult mice (Bernitz *et al.*, 2016). Considering the bias toward the myeloid lineage, defined by CD41 expression, the HSC dynamics can be described by the following system of ODEs (Fig. 2):

4 step symmetric division model

Fig. 2 Division scheme of HSCs with aging. Mathematical model describing the dynamics of aging HSCs. (A) $x_n(t)$ denotes the number of HSCs that have divided n times ($n=0, 1, 2, 3, 4$) at time t , and $1/k_n$ is the expected time interval to the next division for a cell that has previously divided n times. (B) $x_n(t)$ and $y_n(t)$ denote the number of CD41⁻ and CD41⁺ HSCs, respectively, that have divided n times at time t . A fraction α of the divided cells in the CD41⁻ HSC population migrate into the CD41⁺ HSC population.

$$\begin{aligned}
 dx_0(t)/dt &= -k_0x_0(t) \\
 dx_1(t)/dt &= 2(1-\alpha)k_0x_0(t) - k_1x_1(t) \\
 dx_2(t)/dt &= 2(1-\alpha)k_1x_1(t) - k_2x_2(t) \\
 dx_3(t)/dt &= 2(1-\alpha)k_2x_2(t) - k_3x_3(t) \\
 dx_4(t)/dt &= 2(1-\alpha)k_3x_3(t) - k_4x_4(t) \\
 dy_0(t)/dt &= -k_0y_0(t) \\
 dy_1(t)/dt &= 2k_0y_0(t) + 2\alpha k_0x_0(t) - k_1y_1(t) \\
 dy_2(t)/dt &= 2k_1y_1(t) + 2\alpha k_1x_1(t) - k_2y_2(t) \\
 dy_3(t)/dt &= 2k_2y_2(t) + 2\alpha k_2x_2(t) - k_3y_3(t) \\
 dy_4(t)/dt &= 2k_3y_3(t) + 2\alpha k_3x_3(t) - k_4y_4(t)
 \end{aligned} \tag{3}$$

Here, $x_n(t)$ and $y_n(t)$ are the number of HSCs not expressing and expressing CD41, respectively. The cells have divided n times ($n=0, 1, 2, 3, 4$). In this model, the CD41⁻ HSCs gain CD41 expression at a rate α with each division. Analyzing HSC count data, α was estimated as 0.12, meaning that the cells gain CD41 expression after every ten divisions (Bernitz et al., 2016). In this way, the differentiation rate of HSCs was quantitatively deduced from detailed cell count data and the mathematical model.

Basic Model of BrdU Labeling

Lymphocyte dynamics are commonly quantified by two DNA labeling methods, the BrdU labeling technique introduced in Section “Applications”, and deuterium labeling, which can be provided as heavy water or deuterated glucose. Under deuterium administration, some of the hydrogen atoms of the DNA that was newly synthesized during cell division are replaced with deuterium atoms, which are detectable by mass spectrometry. Deuterium glucose is non-toxic to humans, so is available for quantifying the dynamics of human lymphocytes (Macallan et al., 2003, 2005; Mohri et al., 2001; Ribeiro et al., 2002). Both methods label the DNA of dividing cells. DNA can also be labeled by an intracellular fluorescent dye called carboxy-fluorescein diacetate succinimidyl ester (CFSE) (Lyons, 2000). After measuring the fluorescence intensity of the CFSE-labeled cells, one can determine the distribution of the number of cell divisions undergone by each cell, because (as mentioned above) the fluorescence intensity halves after each cell division. CFSE-labeling data have been analyzed by several ODE models (Revy et al., 2001; Luzyanina et al., 2007), delay equations based on the cell cycle (De Boer and Perelson, 2005) and stochastic processes (Hawkins et al., 2007).

In this subsection, we discuss mathematical models for analyzing BrdU labeling data. The fraction of cells incorporating BrdU is measured by detecting the BrdU antibodies attached to the cells. During BrdU administration, all unlabeled cells become two labeled daughter cells after a cell division, and all labeled cells divide into two labeled daughter cells. After the BrdU administration, the unlabeled cells divide into two unlabeled cells but the labeled cells divide into two labeled daughter cells with diluted

BrdU. Let us assume that a cell inflowing from the outside is labeled during the BrdU administration but is not labeled after the administration is withdrawn (Fig. 3; De Boer *et al.*, 2003a,b; Kaur *et al.*, 2008). The lymphocyte dynamics during the BrdU administration are then described by the following ODEs:

$$\begin{aligned} dL(t)/dt &= s + 2pU(t) + (p-d)L(t) \\ dU(t)/dt &= -(p+d)U(t) \end{aligned} \quad (4)$$

Here, $L(t)$ and $U(t)$ are the fractions of BrdU-labeled and unlabeled cells among the activated lymphocytes, respectively. s is a constant rate of inflowing cells per unit time, and p and d are the proliferation and death rate constants of the lymphocytes, respectively. As the number of total activated cells, $A(t) = L(t) + U(t)$, usually remains constant, we obtain:

$$A(t) = A = s/(p-d) \quad (5)$$

The lymphocyte dynamics after the BrdU administration are described by the following ODEs:

$$\begin{aligned} dL(t)/dt &= (p-d)L(t) \\ dU(t)/dt &= s + (p-d)U(t) \end{aligned} \quad (6)$$

Let R be the number of unactivated lymphocytes. The total number of lymphocytes is then $T = A + R$, and the fractions of BrdU-labeled lymphocytes during and after the BrdU administration ($f_L(t) = L(t)/T$) can be analytically solved as follows:

$$\begin{aligned} f_L(t) &= 100\alpha(1 - e^{-(d+p)t})(t \leq T_{\text{end}}) \\ f_L(t) &= 100\alpha(1 - e^{-(d+p)T_{\text{end}}})e^{(p-d)(t-T_{\text{end}})}(t > T_{\text{end}}) \end{aligned} \quad (7)$$

Here T_{end} represents the end of the BrdU administration, and α is the maximum fraction of BrdU-labeled lymphocytes if the BrdU is sufficiently administrated (i.e., $\alpha = A/T$) (De Boer *et al.*, 2003a,b). Fitting Eq. (7) to the BrdU-labeled experimental data and comparing the estimated parameters α , p and d under different conditions (e.g., health and disease), one can detect the affected process in terms of parameter values. In the macaque study of (Mohri *et al.*, 1998), the replacement rates of CD3 + CD4 + / - lymphocytes (defined as the difference between the death and proliferation rates of the lymphocytes) were approximately two- to three-fold higher in SIV-infected macaques than in uninfected macaques, indicating that SIV infection is associated with heightened lymphocyte turnover (Mohri *et al.*, 1998). Quantified cell dynamics, i.e., the rates of cell division and cell death, can effectively reveal a pathophysiology or the effect of a treatment, and have been reported in many studies (De Boer *et al.*, 2003a,b; De Boer and Perelson, 2013; Kaur *et al.*, 2008; Asquith *et al.*, 2007).

Modeling the Antiviral Effect of IFN

Model (8) is a classical but well-parameterized mathematical model of virus infection, which has been especially applied in cell culture (see Fig. 4; Iwami *et al.*, 2012b; Perelson, 2002; Perelson and Nelson, 1999):

$$\begin{aligned} dT(t)/dt &= -\beta T(t)V(t) \\ dI(t)/dt &= \beta T(t)V(t) - \delta I(t) \\ dV(t)/dt &= pI(t) - cV(t) \end{aligned} \quad (8)$$

Here, $T(t)$ and $I(t)$ are the numbers of target (i.e., uninfected) cells and infected cells, respectively, and $V(t)$ is the viral load at time t . β is the rate constant of the infection. Infected cells die at rate δ per unit time. Viruses are produced from infected cells at rate p per unit time, and degrade at rate c per unit time. To quantify the antiviral effect of IFN on HIV-1-infected cells in culture, Ikeda *et al.* (2015) proposed the following extended mathematical model of target cell growth:

Fig. 3 BrdU-labeling scheme during and after administration. BrdU-labeling dynamics of a leukocyte population. $L(t)$ and $U(t)$ denote the numbers of labeled and unlabeled cells, respectively, at time t . In the labeling phase, unlabeled cells become labeled after cell proliferation and outside cells flow into the population of labeled cells. In the non-labeling phase, outside cells flow into the population of unlabeled cells.

$$\begin{aligned}
dT(t)/dt &= gT(t)(1 - (T(t) + I(t))/T_{\max}) - (1 - \eta)\beta T(t)V(t) \\
dI(t)/dt &= (1 - \eta)\beta T(t)V(t) - \delta I(t) \\
dV(t)/dt &= (1 - \varepsilon)pI(t) - cV(t)
\end{aligned} \tag{9}$$

In Model (9), IFN is assumed to inhibit *de novo* infection and virus production at rates η and ε , respectively ($0 < \eta, \varepsilon < 1$). By fitting Eq. (9) to the experimental cell-culture data in the presence and absence of IFN, Ikeda *et al.*, (2015) found that IFN is at least two-fold more effective against *de novo* infection (η) than against virus production (ε). As discussed in landmark papers (Neumann *et al.*, 1998; Dixit *et al.*, 2004), mathematical modeling can extract the unknown action mechanisms of antiviral drugs from experimental and clinical data.

Illustrative Examples

All models in Section “Analysis and Assessment” were derived from the generalized mathematical model Eq. (1) introduced in Section “Fundamentals”.

In Model (2), the $-k_n x_n(t)$ terms denote emigrations from cell populations that have divided n times (n th-population cells) to populations of cells that have divided $n + 1$ times ($[n + 1]$ th- population cells) by cell division (i.e., k_n corresponds to d_{ij} , $i = x_n$, $j = x_{n+1}$). Immigrations from the n th population to the $(n + 1)$ th population are described by $2k_n x_n(t)$, because cells divide into two daughter cells (i.e., k_n corresponds to d_{ij} , where $i = x_{n+1}$, $j = x_n$, and $2k_n$ corresponds to h_{ij} , where $i = x_{n+1}$, $j = x_n$). In Model (3), the $CD41^-$ cells emigrated from the n th population divide into two daughter cells, which then immigrate to the $(n + 1)$ th populations of $CD41^-$ cells at a rate of $1 - \alpha$, or to the $(n + 1)$ th population of $CD41^+$ cells while gaining $CD41$ expression at rate α . In this case, $2(1 - \alpha)k_n$ corresponds to h_{ij} , where $i = x_{n+1}$, $j = x_n$, and $2\alpha k_n$ corresponds to h_{ij} , where $i = x_{n+1}$, $j = y_n$. The emigrated $CD41^+$ cells of the n th population divide into two daughter cells and immigrate to the $(n + 1)$ th population of $CD41^+$ cells. In models (2) and (3), the proliferation and death processes are omitted because both daughter cells generated by the cell division migrate to the next population and HSCs are not assumed to die within the time scale of the experiment.

In Model (4), the emigrated unlabeled cells ($-pU(t)$), which divide into two daughter cells and become labeled by BrdU, immigrate into populations of BrdU-labeled cells ($2pU(t)$) during the BrdU administration (i.e., p corresponds to d_{ij} , where $i = U$, $j = L$, and $2p$ corresponds to h_{ij} , where $i = L$, $j = U$). Outside cells immigrating into a population of BrdU-labeled cells are described by s , because all such cells are assumed to be labeled by BrdU. The terms $-dL(t)$ and $-dU(t)$ denote a cell death event among the BrdU-labeled and unlabeled cells, respectively (i.e., d corresponds to a_i , where $i = L, U$). In Model (6), the BrdU-labeled and -unlabeled cells proliferate and die at rates p and d after BrdU administration, respectively (i.e., p corresponds to p_i , with $i = L, U$, and d corresponds to a_i , with $i = L, U$). Outside immigration into a population of unlabeled cells is described by s because all such cells are assumed to be unlabeled (i.e., s corresponds to d_{ij} , where $i = L$ and $j = \text{outside}$).

In Model (8), the term $\beta T(t) V(t)$ describes a migration event from the target cells into the virally infected cells (i.e., a new viral infection of a target cell). This migration rate $\beta V(t)$ assumes that the target cells and viruses are well-mixed and that all target cells encounter all viruses at the same frequency (i.e., $\beta V(t)$ corresponds to d_{ij} , where $i = T$, $j = I$). The infected cells die by cytopathogenesis at rate δ (i.e., δ corresponds to a_i , with $i = I$). Immigration into the virus population is denoted by $pI(t)$, which describes the newly produced viruses from infected cells (i.e., p corresponds to h_{ij} , where $i = V$, $j = I$). In Model (9), the cell-growth term $gT(t)(1 - (T(t) + I(t))/T_{\max})$ is a form of the “logistic equation” (i.e., $(1 - (T(t) + I(t))/T_{\max})$ corresponds to p_i , with $i = T$). Migrations from the target cells into the infected cells by infection, and immigrations into the virus population by viral production in infected cells, are inhibited at rates $(1 - \eta)$ and $(1 - \varepsilon)$ by the antiviral effects of IFN, respectively. In this case, $(1 - \eta)\beta V(t)$ corresponds to d_{ij} , where $i = T$, $j = I$, and $(1 - \varepsilon)p$ corresponds to h_{ij} , where $i = V$, $j = I$.

Results and Discussion

Mathematical modeling of experimental systems is important for obtaining quantitative results. However, the estimated parameters and the interpreted results of a data analysis depend on the experimental system and/or formulation of the mathematical model. Therefore, the assumptions underlying these models should be biologically reasonable. When several mathematical models can conceivably describe the analysis result, immunologists must base their choice on the precise assumptions underlying the different models (De Boer and Perelson, 2013). Moreover, when developing a mathematical model based on the generalized model (1), the modeler should include only those cell populations and interactions with a sound scientific or immunological basis.

For example, the cell population dynamics in Model (3) are distinguished by the number of cell divisions undergone by each cell, and by the presence or absence of $CD41$ expression (Ito *et al.*, 2017; Bernitz *et al.*, 2016). On the one hand, this mathematical model sufficiently estimates the rate at which $CD41^-$ HSCs gain $CD41$ expression from the cell-division number distribution in the presence or absence of $CD41$ expression, which was experimentally determined. On the other hand, Model (4) considers two subpopulations of the activated lymphocytes (BrdU-labeled and BrdU-unlabeled). Mathematical models of BrdU-labeling, regardless of their formulation, are known to robustly estimate “average turnover” (De Boer *et al.*, 2003a,b). Thus, under clear assumptions, a theoretical study is advantageous for understanding the relationships between different mathematical models. Viral infection models of target cells, infected cells and viruses are also derived from the generalized model (1). An example is Model (9), which was established for both clinical and experimental data analysis (Perelson, 2002). Other model branched from this fundamental model including the non-infectious virus population was fitted to the measured concentration of target cells,

Fig. 4 Infection scheme including the effect of INF. Dynamics of HIV-1 infection, showing the anti-viral effect of INF on *de novo* infection and virus production. $T(t)$ and $I(t)$ denote the number of target (uninfected) cells and infected cells at time t , respectively. $V(t)$ denotes the viral load at time t . In this model, target cells are infected with viruses at rate β and infected cells produce viruses at rate p . The inhibition rates of infection and virus production by INF are η and ϵ , respectively.

concentration of infected cells, total viral load, and infectious viral load. From the fittings, the production efficacy of infectious virus was estimated (Iwami *et al.*, 2012a; Iwanami *et al.*, 2017).

In summary, the simple generalized model (1) can provide novel immunological insights. A deep and mutual understanding between theoreticians and experimentalists can establish a strong collaboration of mathematical models and experimental data.

Future Directions

Various experimental methods for cell counting and data analysis have been established in the last 20 years. The coupling of experimental methods with mathematical models can quantitatively reveal the dynamics of different cell types, as discussed herein. This approach should be followed by mathematical models and computer simulations that reveal the complex, hierarchical effective interactions among immune cells that maintain homeostasis. Recall that a failure of this balanced system leads to a diseased state. For example, osteoimmunology is an interdisciplinary field that tries to link immunological interactions to the mechanisms of bone formation and bone resorption (Takayanagi, 2007). Osteoblasts and osteoclasts interact through cytokines represented by RANKL, a member of the tumor necrosis factor family of cytokines. RANKL also works in the immune system. These interactions maintain the balance of bone formation and bone resorption. When this balanced interaction fails, bone diseases such as osteoporosis and fibrodysplasia ossificans progressiva will develop. The generalized model (i.e., Eq. (1)) and its derived version are appropriate and suitable for elucidating the mechanisms of these complex immune-related diseases.

Closing Remarks

Immunological research has greatly benefitted from experimental techniques in molecular and cell biology, which have rapidly advanced in recent years. However, many of these experimental techniques elucidate only one aspect of immunological phenomena. In tandem with rigorous experimental work, mathematical modeling offers an excellent opportunity for comprehensively analyzing immunological events. At one time, modeling work was essentially ignored by experimental immunologists, but in the last 20 years, it has become an important tool in biological research. In fact, almost all experimental biology groups are now collaborating with a theoretical scientist. Mathematical modeling provides quantitative insights that cannot be obtained by experimental and clinical studies alone. The examples in the present article were selected to highlight these strengths.

Biographical Sketch

Shoya Iwanami I am a graduate student in the mathematical biology laboratory, Department of Biology, in Kyushu University, Japan. I studied biology as an undergraduate student and joined the mathematical biology laboratory in 2015. My research interest is quantifying the biological characteristics of immunology, virus dynamics and stem cells using mathematical models.

Shingo Iwami I am an Associate Professor in the mathematical biology laboratory, Department of Biology, in Kyushu University, Japan. I have been working on theoretical analyses of virus infection *in vivo* and *in vitro* since 2007, covering various infections. My main interest is mathematical modeling and data analysis based on mechanistic models of virus infection dynamics.

Introduction

Bioimaging techniques were developed, which produce images from biological and medical specimens of entire organism, to single molecules and organs (Swedlow, 2012). Common biological imaging methods include magnetic resonance imaging (MRI) computed tomography (CT), X-rays, and positron emission tomography images. These methods are used especially in medical imaging for clinical purposes for vascular, tumor, anatomical, and metabolic imaging and they have a lower resolution. Confocal or two-photon laser scanning microscopy (Pawley, 2006), scanning or transmission electron microscopy, and atomic force microscopy (Keller and Stelzer, 2010) are imaging methods that have higher resolutions commonly used for visualization of cell structures, mapping cell surface, and discerning protein structure (Schmidt *et al.*, 2013). Both the medical and the high resolution imaging techniques are important sources for bioimaging techniques. Methods based on light microscopy are also important to understand the cell structure and function, and which lie between medical imaging and high resolution techniques. Imaging techniques such as photoactivation localization microscopy, fluorescence photoactivation localization microscopy, and stochastic optical reconstruction microscopy provide locations and localization uncertainties of individual molecules accurately up to 20 nm (Betzig *et al.*, 2006; Hess *et al.*, 2006; Rust *et al.*, 2006). Advancement in imaging technologies generates quantitative measurements from images that enhance knowledge and understanding of biological phenomena.

Advances in the field of microscopy in terms of three dimensional (3D) images provides better understanding of biological images (Schmid *et al.*, 2010; Mayer *et al.*, 2012; Guo *et al.*, 2013; Allen *et al.*, 2015). In four-dimensional (4D) imaging, time is the added dimension in the existing spatial dimensions that allows studying biological phenomena in four dimensions. 4D imaging is important in the field of medical imaging such as tumor detection (Handels *et al.*, 2007), changes in tissues intensities (Gorbunova *et al.*, 2012) and cell invasion (Kelley *et al.*, 2017).

Image processing can be used to determine whether an image included specific information or contains some specific objects, features, or activities. The identification task is solved automatically by using a digital image processing field with less human effort. The surge of complex biological and biomedical images leads to the existence of numerous image data analysis and informatics methods to extract quantitative information via segmentation and motion tracking, comparison, search, and management of the biological information of the images (Kvilekval *et al.*, 2010). Bioimage informatics techniques translate image data into valuable biological information (Peng, 2008). Bioimage informatics allows us to discover answers to biological problems from biological and medical specimens of the entire organism, single molecules and organs that would require higher cost to solve (Peng, 2008; Myers, 2012). Bioimage informatics research is heading towards automated invention of models of biological systems and machine learning methods (Murphy, 2014). Obara *et al.* (2012) established an image analysis method to identify and illustrate huge compound fungal networks using a graph representation that can be used for predicting the physiological performance of the fungal system. Puniyani and Xing (2013) used images of *Drosophila* embryo using a supervised learning method to understand gene interaction networks. Liu *et al.* (2012) developed a phenotype recognition model using zebrafish embryos' development response towards HTS toxicity. Aging is studied using phenotypes described in *C. elegans* upon different levels of mitochondrial alteration to develop an automated high-content strategy to identify new potential pro-longevity interventions.

Coelho *et al.* (2015) developed an automated quantification and identification of neutrophil extracellular traps (NETs) using supervised machine learning method that is important in controlling bacterial pathogens. Deep convolutional neural networks have been used for automated segmentation of bacterial and mammalian cells and identification of wild animal species in camera-trap images (Sadanandan *et al.*, 2017; Gomez and Salazar, 2016; Villa *et al.*, 2017). Perre *et al.* (2016) applied image analysis techniques to automatically identify invasive fruit fly species based on wing and aculeus images.

Mosleh *et al.* (2016) developed a program for automated cephalometric analysis to identify important landmarks point in the human skull that can also be applied to species identification. Computerizing cephalometric is important to lessen the time required for orthodontic procedures by providing X-ray enhancement, consistent measurements, presurgical simulation. Cephalometric analysis can be extended to include species classification.

Automated image recognition has been used to identify various species of algae and harmful species of algae to access environmental condition in aquatic habitat (Mosleh *et al.*, 2012; Verikas *et al.*, 2012; Luo *et al.*, 2011; Dimitrovski *et al.*, 2012; Coltelli *et al.*, 2014). Identification of flatworms is important for preservation of marine life was conducted by Kalafi *et al.* (2016) using images of hard parts of the haptor organs of flatworms with machine learning approach for classification. Nguyen *et al.* (2016) proposed a method SLIC-MMED (simple linear iterative clustering on multichannel microscopy with edge detection) that is able to segment muscle fibers and can be applied to stem cell regeneration and cell lineage tracing. Savkare and Narote (2012) and Rosado *et al.* (2016) used image processing approach to extract red blood cell and classify them as normal or malaria infected cell. Intarapanich *et al.* (2016) developed an object-based extended depths of field method to obtain a clear focus image of the foreground properties of the image which constitutes important features. This can be applied in medical diagnostic applications

such as diagnosis of malaria infection that can considerably lessen image processing time while preserving significant image features.

Quantitative information resulting from microscopy bioimages is important to enhance understanding of biological processes. With the advancement in imaging technology, image processing techniques are in dire need. There is vast amount of studies conducted on basic image processing, however there very is little information on image processing methods that involves bioimage informatics. Furthermore the absence of high-quality precise data sets for assessment of various common bioimage analysis methods is the main obstacle. A high-quality, well-defined data set for bioimage analysis consists of benchmarked data with well-defined verified and validated structure that is the gold standard for bioimage analysis. A benchmarked dataset reduces analysis and evaluation time and is important for assessing performance, consistency, and accuracy of methods in bioimage analysis (Gelasca *et al.*, 2009).

The important procedures of bioimage informatics include bioimage acquisition, visualization, analysis, and management. Bioimage informatics also covers creation and understanding of biological information generated from biomages using image processing, data mining, machine learning, and pattern recognition methods.

In this article, image acquisition and processing, image segmentation, feature extraction, feature selection, classification registration, and annotation are discussed. Examples and an appropriate case study are provided in each section.

Image Acquisition and Preprocessing

Digital images are produced by image equipment and the process of transferring the analogue image into digital images using imaging devices is image acquisition. The main unit of digital images is pixel which represent the values correspond to the light intensity in one or more spectral bands. Image acquisition is a crucial stage in bioimage informatics related research and automated systems (Coltelli *et al.*, 2014). Captured microscopy images usually suffer from problems such as varying in colors, darkness, resolution, contrast, and brightness that is related to light source, lens, and method of capturing. Microscope images also include unavoidable scum existing beside target cells, and some holes or small objects that strongly affect image quality. Images may contain unwanted areas, shadows, and appear blurry. The preprocessing of captured images is a preparation and treatment process used to enhance the features of images to produce clearer details, remove noise, remove intelligibility of images, and improve the overall appearance of images. Image enhancement is defined as the conversion of an image quality to create a clear image and ensure the accuracy of the process of segmentation and feature extraction. Some common techniques used in image enhancement include image conversion to grayscale, filtering, histogram conversion, and color composition. Kho *et al.* (2017) converted the RGB value of a leaf image to HSV value to remove shadow and to ensure clear image contrast for image segmentation and feature extraction as depicted in Fig. 1.

Differences in light or brightness can be reduced using histogram equalization method and contrast enhancement in images can be carried out by stretching the histogram of digital image (Gonzalez and Woods, 2007). Histogram equalization can be applied to enhance the contrast of the color image intensity before the image is converted into a gray scale image. The frequency occurrence of pixel intensities given by the histogram image intensity was adjusted to increase image contrast. Histogram equalization is one type of gray scale conversion; it used to convert the histogram of the original image into an equalized histogram. An accumulated histogram was calculated from original image and then divided into a number of equal regions. The corresponding gray scale in each region was assigned to a converted gray scale. The effect of histogram equalization was the enhancement of image parts that have more frequency variation, whereas parts of an image with less frequency were neglected. Fig. 2 shows a comparison between the original and converted images after histogram equalization was applied, and shows a comparison between the histogram of the original image with the histogram of a produced algae image.

Images acquisition condition such as parameter and equipment should be consistent and images should be of high-quality with clear details and less noise. Applying resampling method, reducing sensor noise and contrast enhancement can increase the quality of image being captured. Images captured using different equipment should be labeled with scales. Problem related to using different equipment in medical images may produce images that are not alike in appearance. Images can contain noise such

Fig. 1 Shadow removing image preprocessing. Thin streak of shadow can still be seen in (c), which is then removed in (d).

Fig. 2 Examples: Histogram equalization application process as (a) Original image of *Oscillatoria* sp., (b) Result image after equalization, (c) Accumulated histogram of original image, (d) Accumulated histogram for grayscale image.

as Gaussian film grain, nonisotropic, speckle and periodic noise, and salt and pepper noise from imaging equipment that can reduce the image quality especially salt and pepper noise in medical images (Sánchez et al., 2012). Noise is added into an image at the time of image acquisition or image capturing. Noise reduction is necessary to preserve the quality of image. Noise reduction filters are comprised of linear, nonlinear, adaptive, median, and fuzzy filters (Mythili and Kavitha, 2011). The main purpose of the filters is to produce a high-quality image by sharpening, edge highlighting, and contrast improvement. High-quality images are important for image processing especially medical images. Some of these developed filters to enhance image quality are median filter, a nonlinear filter used mostly to reduce image noise in better way than other methods such as convolution approach (Lim, 1990). Fig. 3 illustrates application of median filter to algae species. Median filters have been applied by Kho et al. (2017) to remove noise from a leaf image and Barry and Williams (2011) for fungal network extraction.

The Kalman filter an adaptive filtering approach for color noise based on the correlative method (Xinding et al., 1996). The Gaussian filter is an image-blurring filter that uses a normal distribution, also called Gaussian distribution, for calculating the transformation to apply to each pixel in the image. It is used widely to filter medical images to remove fine detail and noise (Yue et al., 2006). Gaussian filters are also used to smooth the input image (Yue et al., 2006). Gaussian filters can separate the holes from the noise in gray image region filters to smooth gray images for contrast enhancement. Gaussian filters are widely used for detection of edges and peaks in images. Unsharp filters are used to filter low spatial frequencies from the image data to enhance the image. An X-ray or clinical medical image generally suffers from low contrast quality and degradations that vary from one region to another. Unsharp filtering or masking is an edge-enhancement technique by isolating the edges in an image, amplifying them, and then adding them back into the image. The unsharp filter and Gaussian filter are the most common filters used for medical image filtering (Chalazonitis et al., 2003).

In X-rays of hard and soft tissue in a cephalometric system image quality influences the accuracy of locating landmark points automatically. High-quality images are important to identify landmark points automatically as manual identification is not accurate (Mosleh et al., 2016). X-Cephalometric images are the basis of cephalometric measurement and analysis, which have been widely applied in the fields of orthodontics and provide a scientific basis for making the diagnosis, treatment, and accurate and effective prediction. The cephalometric system analysis requires good quality X-rays. If the X-ray is poorly exposed, the lines are fragmented. The critical lines defining the landmarks may not be tracked properly. The quality of images directly influence accuracy of locating landmarks. The original image must be filtered to ensure the accuracy of locations and measurements. During sampling and transmission, images are often degraded by noises that originated from a multiplicity of sources. These noises are colorful and their variances are not known beforehand. The original images must be filtered to ensure the accuracy of location and measurement. Mosleh et al. (2016) applied unsharp and Gaussian filters to enhance image properties for feature extraction. Unsharp filters in this

Fig. 3 Median filter application (a) *Oscillatoria* sp. image in gray scale before the process (b) *Oscillatoria* sp. after median filter was applied.

study are used for sharpening of X-ray images in the presence of low noise levels via an adaptive filtering algorithm. Adaptive filtering using these kernels can be performed by filtering the image with each kernel, in obtaining the output image with sharp filter. Gaussian filters are designed to give no overshoot to a step function input while maximizing the rise and fall time. This behavior is closely connected to the fact that the Gaussian filter has the minimum possible group delay. The gradient operators in a Gaussian filter enhance image edges and at the same time enhance noise. Emphasizing the fine details of a radiographic image while suppressing noise is possible by employing a median filter prior to applying a gradient operator. Approximations to the pill box blur and Gaussian low pass. The idea of Gaussian smoothing is to use this 2-D distribution as a point-spread function, and this is achieved by convolution. Before the convolution is performed a discrete approximation to the Gaussian function was produced. In theory, the Gaussian distribution is nonzero everywhere, which would require an infinitely large convolution kernel, but in practice it is effectively zero when it is more than three standard deviations from the mean (Davies, 1990).

Gaussian filter is generated with some parameters as a 2-D array because the X-ray image is a 2-D array. Input is the unfiltered X-ray image and the output is the filtered X-ray image. Both implemented filters can work in real time at system runtime.

Fig. 4(a) illustrates X-ray images without and with filtering. The low intensity contrast that is almost hidden in the background in **Fig. 4(a)** can be distinguished clearly in **Fig. 4(b)** and **Fig. 4(c)**. The image in **Fig. 4(a)** is considered a slightly overexposed cephalometric radiograph. The contrast of the bone anatomical structures is quite satisfactory, but soft tissue tends to mix with the background in some zones. After the application of unsharp filter as shown in **Fig. 4(b)** or Gaussian filter as shown in **Fig. 4(c)**, the bone contrast is greatly improved, and anatomical structures become more visible.

Image Segmentation

Microscopic images normally contain different objects, therefore image processing is required to isolate the image into different object components. Detection processes for specific image points or regions are performed to determine the object for further processing. This process of isolating and dividing the image into a subimage, where each image contains at least one object, is called segmentation. Segmentation is an essential phase in image processing, which is carried out after image processing and before feature extraction and classification (Haralick and Shapiro, 1992). The image segmentation process is used to isolate

individual objects in captured images. The segmentation process is important for quantification and analysis of bioimages. There are numerous image segmentation methods such as the thresholding based method, clustering based method, edge based method, region growing based method, watershed method contour based method, and model based method (Basavaprasad and Ravi, 2014). The thresholding based segmentation method is a common method for image segmentation that is applied to the image pixels. This method can be categorized into otsu, global, and local thresholding techniques. Rosada *et al.* (2016) reviewed numerous methods involved in automated malaria cell segmentation where the thresholding based method is most commonly applied. In bioimage segmentation the otsu based method has been applied in identifying *Drosophila* egg stages (Jia *et al.*, 2016), identification of herbs leaves and plant disease identification (Isnanto *et al.*, 2016; Akhtar *et al.*, 2013).

Edge based segmentation is another common method and is implemented using filters such as Canny's, Sobels, Laplacian, Robert, and gradient filters (Gonzalez and Woods, 2007). A Canny edge detector is considered as the most powerful edge detector for image segmentation (Canny, 1987). It is used to identify discontinuities in an image intensity value or the edge of the image and it has been used widely in species identification (Kalafi *et al.*, 2016; Mosleh *et al.*, 2012; Murat *et al.*, 2017). Both Canny and Sobel have been applied in automatic identification of algae due to substantial edges and shapes of the species (Santhi *et al.*, 2013).

Thresholding based method together with edge based method have been applied in Munisami *et al.* (2015) for plant leaf recognition and brain tumor detection (Manasa *et al.*, 2016). Identification of bioimage segments is often more effective when making use of boundaries and shape information extracted by segmentation methods. The Grabcut algorithm (Rother *et al.*, 2004) is a segmentation technique used in automated identification of species systems (Hernández-Serna and Jiménez-Segura, 2014) to remove background. In this technique, hard segmentation made by iterative graph-cut optimization is combined with border matting to get rid of mixed and blurred pixels on the boundaries of an object.

Overlapping objects in microscopic images makes object detection difficult. There have been various methods to separate overlapping objects including watershed algorithm, edge detection method, morphological erosion, active contour method, and others. The application of the edge detection method together with morphological erosion and dilation are implemented in

Mosleh *et al.* (2012) in automatic algae detection. In morphological operations, the value of each pixel in the output image was compared with the corresponding pixel in the input image of its neighbors. Fig. 5 illustrates application of morphological operation and Canny edge detection.

The edge detection method does not perform well in instances where the overlapping objects are intensely textured or there is no noticeable intensity variance between the overlapping. The active contour and snake methods (Kass *et al.*, 1988) require high computer processing capacity and it not suitable for large objects. It has been used by Chopin *et al.* (2016) to determine in identification of wheat leaves and Sabeena Beevi *et al.*, (2017) in identification of mitotic nuclei from microscopy images of breast histopathology slides.

The watershed method is considered as an effective and efficient method to separate overlapping objects (Savkare and Narote, 2012). Watershed method segmentation is also used to detect and extract a graph representation of complex curvilinear networks and overcomes a critical bottleneck in biological network analysis (Obara *et al.*, 2012). Segmentation of globular object can be challenging due to object irregularity. This requires additional step such as hole filling before applying watershed segmentation method (Long *et al.*, 2007). Yang and Ahuja (2014) used local density clustering to identify pixels that matter before the watershed algorithm is used to separate the overlapping objects in blob or granular object recognition for cell/nuclei segmentation. Automatic segmentation of cell nuclei in microscopic images is highly desirable, however it is difficult due to huge intensity inhomogeneities in the cell nuclei and the background. Unsupervised methods are popular for cell nuclei segmentation thresholding, *k*-means clustering, watershed, active contour, level set and graph-based models. Thresholding, *k*-means, and watershed are applicable when there is great contrast between object and background and it is not suitable with images with inhomogeneities.

Other techniques such as *k*-means clustering, which attempts to minimize the variance of intensity values within a predefined number of clusters, and Gaussian mixture models (GMM) (Permuter *et al.*, 2006), which use probability distributions to classify pixels as foreground or background. GMM has been used in the brain segmentation of magnetic resonance images (MRI) due to ease of use and high contrast between different tissue classes of the brain (Song *et al.*, 2014). Combination of *k*-means clustering and otsu method was applied in identification of plant leaf disease after RGB color transformation on leaf. *K*-means clustering was used to divide a leaf image into segments to identify disease where the leaf is infected by more than one disease (Al-Hiary *et al.*, 2011).

Chopin *et al.* (2016) applied hybrid segmentation technique for whole plant such as wheat image segmentation comprising the leaf tips and twists. Initial segmentation was done using GMM, *K*-mean, and multidimensional histogram thresholding and active contour model by Kass *et al.* (1988), and applied to enhance the segmentation after identification of control points in the image.

Before feature extraction is applied, images, especially species or plant images, need to be aligned. Mosleh *et al.* (2012) applied techniques for image objects alignments. This method also has been adopted by Kho *et al.* (2017) in *ficus* plant leaf identification. This technique performs automatic rotation for objects to be aligned with the horizontal axis, which increases the classification accuracy. A small routine is developed to obtain the angle of inclination for an object automatically. This routine is then used for rotating image objects to be aligned horizontally as shown in Fig. 6.

The angle of inclination is calculated automatically by obtaining the longest path between each two points on the object boundary. Identified point $P_1(X_1, Y_1)$, $P_2(X_2, Y_2)$, and Origin point $P(0, 0)$ are used to determine the angle of inclination using the following equation:

$$\theta = \tan^{-1}(m_1 - m_2)/(1 + m_1 * m_2) \quad (1)$$

where m_1 and m_2 are the slopes of lines that form the angle that is obtained using the following equations:

$$m_1 = (Y_2 - Y_1)/(X_2 - X_1) \quad (2)$$

$$m_2 = (Y_1 - Y_0)/(X_1 - X_0) \quad (3)$$

This routine is designed to align the rotated shape into horizontal lines, which will ease the feature extraction process, and improve the accuracy and performance of the recognition process by ensuring that all the extracted features are calculated with similar positioning of the object coordinates.

Fig. 6 Sample steps of auto-orientation method.

Feature Extraction

Features extraction and selection is a crucial step as features extracted from bioimages will be used for bioimage identification. Selection of significant features from bioimages is important as the number of features extracted can be large and this can lead to heavy computational effort. Feature selection allows an optimized number of features being selected. The success of bioimage feature extraction and selection techniques is determined by the quality of the extracted data and the type of classifiers used in bioimage identification and recognition (Chora's, 2007; Kiranyaz *et al.*, 2011).

Feature extraction is a process to obtain useful information from the segmented bioimages that can be used to classify or identify them. Feature extraction is necessary for successful bioimage classification. Features used in bioimage classification normally are a combination of several types of features (Song *et al.*, 2016). There are three distinct features: Texture, shape, and color (Islam *et al.*, 2008; Pin Tian, 2013).

Color is the most significant feature for image classification (Seyyid, 2015; Chora's, 2007). Color histograms, coherence vector, moments, correlogram, scalable color descriptor, dominant color descriptor, and structure color descriptor are various methods to extract color features in an image that are based on mean, skewness, and standard deviation of an image pixel. Color histogram is the most common method to detect color distribution in an image that meets basic requirements meanwhile color moment is the simplest method to implement (Pin Tian, 2013; Seyyid, 2015). In automated identification of zebrafish embryo development in response to toxicity, color features such as scalable color descriptor, color layout descriptor, and color histogram with texture features gave successful results (Liu *et al.*, 2012). Color variance is an important feature in skin cancer detection (Bhuiyan *et al.*, 2013). Chopin *et al.* (2016) used color of leaf together with the direction and magnitude of leaf edges in whole plant identification.

Texture features are significant as well however it is used with other features such as color and shape to enhance its effectiveness. Texture features are important in digital image identification especially in plant leaf identification (Brilhador *et al.*, 2013; Jamil *et al.*, 2015). Combination of texture and shape feature produced better identification in plant leaf identification than using combination of texture, shape and color (Jamil *et al.*, 2015). Texture features should be used as an input when color or shape features are not distinctive enough on the plant species images (Camargo and Smith 2009). Textures features are categorized into statistical and structural features such as Haralick, Gabor, and wavelet and Fourier transform, co-occurrence matrices, shift-invariant principal component analysis, and Tamura features (Chora's, 2007). The Gabor filters compared to gray level co-occurrence matrix for image segmentation and classification can be utilized as is or converted into feature vectors (Kumar *et al.*, 2015). Al-Hiary *et al.* (2011) used texture features derived from co-occurrence matrix with color features to identify plant disease. Camargo *et al.* (2009) used color features together with shape and texture features to enhance identification of visual symptoms of plant disease. Akhtar *et al.* (2013) combined Haralick texture features (Haralick *et al.*, 1973), discrete cosine transform (DCT), and discrete wavelet transform (DWT) features for automatic identification of plant disease.

Combination of Haralick texture features, Pearson correlation between channel intensities, and SURF features (Bay *et al.*, 2008) was used to automatically identify NETs images (Coelho *et al.*, 2015). Texture feature based on DWT is important for bioimage classification of cancerous cells. However in breast cancer cell diagnosis complex daubechies wavelet transform (CDWT) performed better than DWT with color features (Niwas *et al.*, 2013). In identification mitotic nuclei from images of breast histopathology shape and textures features are used (Beevi *et al.*, 2014). Morphological changes of *Caenorhabditis elegans* (*C. elegans*) is used for studying aging due to the small size, transparent body, well-characterized cell types and lineages. An automatic image processing method for both normal and abnormal structures is contrasted using geometric, intensity, and texture features that describe the properties of nuclei in *C. elegans* (Zhao *et al.*, 2017).

Shape feature is important in bioimage object identification. The shape feature extraction method can be categorized into contour based and region-based techniques. Shape features typically comprises of geometric features such as aspect ratio, circularity and irregularity. Advance method for shape features is feature moment such as Zernike moment (ZM) a region-based descriptor. Detailed descriptions of shape based features are explained in Mingqiang *et al.* (2008). Shape, size scale-invariant feature transform (SIFT) are used in identification of cell nuclei in microscopic images (Song *et al.*, 2013). Kalafi *et al.* (2016) extracted various shape features from anchors and bars of monogeneans such as Euler number, perimeter, area, density, and bounding box. Automated stage identification of the *Drosophila* egg chambers includes morphological shape features such as egg chamber size, oocyte size, egg chamber ratio and distribution of follicle cell (Jia *et al.*, 2016).

Shape feature is the most common feature used in plant leaf identification (Jamil *et al.*, 2015). Spatial interrelation shape feature such as convex hull, morphological shape feature of plant, distance features, and color histogram have been used in plant leaf recognition (Munisami *et al.*, 2015). Convex hull allows segmentation of a complex object into a polygon without holes that are convex in nature and shape is very essential in object recognition (Jayaram and Fleyeh 2016). An herbal plant leaf identification system (Isnanto *et al.*, 2016) is based on the shape of the herbal plants' leaf region-based invariant feature extraction or Hu's seven moment invariants. Hu's seven moment invariants are indifferent against translation, scaling, and rotation, as well as in mirror position of the herbal leaf. A combination of shape features using SIFT, color using color moment, and texture feature using segmentation-based fractal texture analysis (SFTA) in herbal plant identification gave better results compared to using a single feature (Jamil *et al.*, 2015). A combination of shape features, texture, and color features have also been applied successfully in classification of plant leaves and algae recognition (Kho *et al.*, 2017; Mosleh *et al.*, 2012).

Below are examples of shape feature extraction based on Mosleh *et al.* (2012). In this study, a specific feature set was selected to obtain the essential characteristics for the selected algae. Feature extraction process is implemented to extract some parameters

Fig. 7 Example of area extraction on algae species.

from both binary and color images of algae including shape index, area, perimeter, minor and major axes, centroid, equivalent perimeters, bounded box, and Fourier spectrum with principal combination analysis (PCA). Other features were derived from the main feature to obtain the relation between shape parameters such as that between area and parameters.

(1) *Area*

The area represents the actual number of white pixels in the selected region. It is calculated by using the number of white or "1" pixels inside the image object as shows in Fig. 7. Area is used as a parameter in classifying operations because it gives an indication of the size of objects.

(2) *Perimeter*

The perimeter of the object is the summation of the distance between each adjoining pair of pixels around the object border, as shown in red pixel in Fig. 8.

(3) *Major and minor axes*

Major and minor axes are extracted where two points are identified automatically by calculating the maximum distance between given points in the objects vector. The major axis represents the line segment connecting between the base points in the X axis, whereas the minor axis represents the maximum width which is perpendicular to the major axis. The major axis can be used as object length and minor axis as object width as represented on Fig. 9.

(4) *Object width factor*

Object width factor is a customized shape feature developed for algae feature extraction that can be applied for any plant images. It is calculated by slicing across the major axis and parallel to the minor axis, the feature points are normalized into a number of vertical strips, and for each strip, the ratio of strip length to the object width is calculated using the following equation: $R_c = W_c/L$, where R_c is the ratio at column c , W_c is the width of object at column c , and L is the object length as shown in Fig. 10. This feature is used to differentiate between some algae that is identical in width and length, and have some essential variations in width at different positions such as *Navicula*, which has similar value of width as *Oscillatoria* at the middle position; however values of width vary in different positions as illustrated in Fig. 10.

(5) *Equivalent diameter*

Equivalent diameter is the feature that determines the diameter of a circle with the same area of a segmented image. It is computed as:

$$\text{EquDi} = \sqrt{4 \cdot \text{Area} / \pi}$$

(6) *Euler number*

This feature is suitable to identify the number of holes inside the image object. The Euler function segments the image before it is filled by holes. The Euler number is equal to the number of objects in the region minus the number of holes in those objects. Fig. 11 shows one example of using Euler number to improve classification method of algae and plant leaf recognition.

Fig. 8 Perimeter feature extraction.

Fig. 9 Major and minor axes.

Fig. 10 Slicing process on *Navicula* and *Oscillatoria*.

(7) Bounding box

Bounding box is identified as the smallest rectangle that contains the region. The box has four feature parameters, including the left corner point of the rectangle (X_1 , Y_1), length, and width of bounding rectangle. **Fig. 12** shows an example for the bounding box object. The rectangle bounding the object is used to compute the extent parameter, which represents the proportion of pixels in the bounding box within the region. The results are obtained by dividing the object area with the area of the bounding box.

(8) Centroid

The centroid is the center of mass for the segmented region, and helps us determine the object center coordinates. The elements of the centroid are two points, the x - and y -coordinates, of the center of mass. **Fig. 13** represents the centroid of an object as small blue star in the center of the object.

The centroid as parameter does not provide a distinguishing feature for selected algae however it can be used to derive a new feature to enhance the classifications method. The centroid coordinate is used to extract the length and slope of the line that connects between the centroid coordinate points and the left corner point extracted from the bounding box; the line is shown also in **Fig. 13** in blue.

(9) Derived features

Selected feature ratios are used for improving the classifying process such as the ratio of the area and perimeter (perimeter/area), ratio of perimeter and object length (perimeter/length), ratio of perimeter and object width (perimeter/width), and ratio of minor to major axes (minor/major).

Fig. 11 Euler number for *Chroococcus* sp.

Fig. 12 Bounding box feature example.

Fig. 13 Illustrates centroid and slope lines.

(10) *Shape index*

Extracted shape index is one of the customized features constructed in this study. Algal taxonomy based on algal shapes is used to develop a new function that can categorize algal shape into three different types: Circular, spiral, and irregular. This function is designed to identify algal shape type and provided us with a new feature called shape index, which is equal to "1" if the shape is circular, "0.5" if the shape is cylindrical, "0" if the shape is spiral, and "−1" if the shape is irregular. This classifier is used to improve accuracy rate and optimize the time of recognition process (Abdullah, 2013). The results obtained from shape extraction will be included as one of the input parameters for algal classification using MLP. The shape index feature can be used as an early stage classifier for the algal taxonomy area. The measurement of the shape index is obtained by evaluating the roundness or cylinder of the objects as described in the following steps:

- Comparing the longest and shortest diameters for the object.
- Comparing the area with the formula $\pi \times r^2$.
- Comparing the perimeter with the formula $2\pi \times r$.
- Eccentricity is also used to improve the results of shape index measurements. Eccentricity refers to the ratio of the distance between the foci of the ellipse bounded the object and its major axis length.

(11) *Entropy of gray image*

Entropy is defined as the statistical measurement of randomness that can be used to characterize the texture of the input image. Entropy is used to extract texture features on the gray scale image. During segmentation processes, the detected object is used to obtain the outline of both color and gray images. Entropy is implemented in our system to obtain one output feature from the outlined gray image.

Fig. 14 Illustrates customized features extraction.

Morphological shape features and Euclidean distance are extracted from a graph representation of complex curvilinear or fungal networks. The approach is generic and can be applied to a wide range of biomedical images (Obara *et al.*, 2012). To further improve efficiency of feature descriptors for particular problem areas, tailored features have been constructed manually for feature extraction from bioimages (Song *et al.*, 2016). Some of the customized shape features for algae and plant leaf detection by Mosleh *et al.* (2012) have been discussed such as object width factor and shape index. Mosleh *et al.* (2016) extracted morphological or shape features for a cephalometric identification system. Tailored feature extraction methods have been constructed to extract line, line angles, and line length. Two points in a binary image are connected if a path can be found between them along which the characteristic function remains constant. Since every selected landmark point has a position in a coordinate system (X, Y), it can be used as parameters to create a line between two selected points as shown in Fig. 14. To perform this operation is a new matrix, which consists of all points between the two points where each generated point is represented by the shortest path in this matrix. Angle measurements are essential for any cephalometric measurement process. The angular measurements module is designed to calculate the size of these angles. Angle is a result of intersection between two lines in a plane, or via connecting all three points. In the two-dimensional space, the angle θ between two lines is the slope of a straight line in the XY plane represents changes of the ordinate Y of the point of the line per a unit-change of the abscissa X of the point. It requires that the line is not vertical. However, in this model angles are considered dimensionless, since they are defined as the ratio of lengths, the unit of measurement is radian. All angle measurements are converted to degree scale instead of radian scale because the degree scale is more standardized and easy to understand for orthodontics specialists. The line measurement of the distance between two points or pixels is constructed using trigonometry given by Pythagoras' theorem, the linear measurements are converted from pixel to inch. Cephalometric line measurements are important because they give information about the skeletal relation. Image resolution and screen resolution is used to calculate the linear measurements in inches. By considering the factor scales, all image types, whatever their resolution, can be analyzed and measured. Scale factor is calculated in our system to minimize the errors of measurement.

Some bioimage software such as BIOimage Classification and Annotation Tool (BIOCAT) and CP-CHARM are image based classification algorithms that are able to extract features without performing segmentation. CP-CHARM algorithm is based on WND-CHARM (Weighted Neighbor Distances using a Compound Hierarchy of Algorithms Representing Morphology) (Orlov *et al.*, 2008). CP-CHARM algorithm is capable of extracting morphological features of an image minus the necessities of segmentation. Features extracted from CP-CHARM are as follows: Moments features, texture features (Haralick, Tamura), edge

features, high contrast features, Gabor features, polynomial decompositions (Fourier, Haar wavelet, and discrete Chebyshev transforms), pixel statistics (histograms, moments), texture measurements, and image levels (transforms and compound transforms) (Uhlmann *et al.*, 2016). CP-CHARM is easier to use and it is an effective substitute to more comprehensive and difficult tools such as BIOCAT (Zhou *et al.*, 2013). Features extraction in BIOCAT comprises of 14 different features such as texture features using DTW, morphological features that comprises of Hu moments, ZMs, Hessian features for identifying tubular features, Gaussian derivatives, and Laplacian features and object statistics (Zhou *et al.*, 2013).

Feature Selection

Feature selection is an important method to construct a classification model that produces higher accuracy rates in bioimage recognition or classification. Feature selection eliminates features that are uninformative, noisy, or redundant, which leads to a dataset that is expressed with important information that is essential for better classification with controlled or little loss of information.

The importance of feature selection method is as follows: It can avoid overfitting of the classification model, provide better understanding into the underlying processes that generated the data, improve model performance, and lower processing time. Feature selection method can be classified into the following three methods: Filter, wrapper, and embedded methods (George and Raj, 2011).

Filter method uses ranking of features based on univariate metric. The top ranking features are utilized in model construction whereas the remaining low ranking features are eliminated. The method is only dependent on training data for feature selection, therefore the results from filter method does not affect model classification. Filter methods evaluate the significance of features by considering solely inherent properties of the data. Filter methods computational requirement are low and are independent of the classification algorithm. Therefore feature selection needs to be executed only once before carrying out classification (Saeys *et al.*, 2007). Brilhador *et al.* (2013) applied correlation feature selection (CFS) method for plant image classification with the Image-CLEF dataset. CFS is an automatic filter based method that identifies features that have no correlation with each other but are greatly correlated with a classification problem (Hall, 1999).

The wrapper method applies a learning algorithm to rank features based on their importance to classification model performance. It is a simple and convenient method of feature selection applicable irrespective of the selected learning algorithm. The learning algorithm is considered as black box. The wrapper procedure involves in using the classification model performance of a particular learning algorithm to evaluate the significant importance of the features. Specific criteria needs to be determined such as on search procedures of features subsets, assessment of machine learning algorithm performance and the type of features to be used. Performance evaluation of the learning classification algorithm is carried out using a cross validation method. Some examples of common classification models are decision trees, naive Bayes, and genetic algorithm (GA). Yusof *et al.* (2013) applied kernel based GA for feature selection from tropical wood texture features. The application of GA produced better results compared with a classification model that did not apply any feature selection. A disadvantage of the wrapper method is the high computational requirements. However this problem can be solved using effective search approaches, which do not sacrifice classification or predictive performance. Such approach involves greedy search strategies; forward selection and backward elimination are computationally beneficial and robust against overfitting. In forward selection, model performance is estimated by adding unselected features to the features subsets. Features that improve model performance are selected. Forward selection procedure is terminated when the expected performance of adding any feature is less than the performance of the feature set already selected. Whereas backward elimination model performance is accessed using all available features and gradually eliminates the least significant ones. The wrapper method is easy to use but embedded methods that incorporate feature selection in the training process might be more effective as there is no need for data splitting into the training and validation set. An example of embedded method is decision trees such as classification and regression trees (CART), which is equipped with a feature selection mechanism (Breiman *et al.*, 1984). The feature selection in an embedded method is built into the classification method. Embedded methods are explicit to a particular learning algorithm. Embedded methods comprise the interaction with the classification model. Examples of embedded methods are random forests (RFs), support vector machine (SVM) and artificial neural network (ANN) (Guyon and Elisseeff, 2003; Saeys *et al.*, 2007). The RF variable importance method has been applied in feature selection of plant leaf; variables with higher mean decrease accuracy are kept and retrained for better classification accuracy (Kumar *et al.*, 2015).

An alternative set of methods are the ones that construct new features from existing features that possibly could lead to loss of information. The methods are linear discriminant analysis (LDA) and principal component analysis (PCA) (Lewis *et al.*, 2012). Landmark localization uses PCA to extract landmarks on the surface of the human face using shape and texture information from 2D data human facial images (Guo *et al.*, 2013). Mosleh *et al.* (2012) in his study applied PCA to extract feature texture for algae classification. CP-CHARM bioimage classification software also utilizes PCA as its feature selection algorithm (Uhlmann *et al.*, 2016). Clustering based algorithms also have been used for feature selection. The most common algorithms comprise *K*-means and hierarchical clustering. Clustering is an unsupervised learning method. Kalafi *et al.* (2016) applied LDA for feature selection in fully automated classification of monogeneans at the species level. Huh *et al.* (2009) applied extension of LDA method for yeast image classification. However this method only works well when the numbers of classes are large as it tends to over reduce features. Stepwise discriminant analysis has been proven to work well in identifying protein in human cancer cells (Xu *et al.*, 2014). Bioimage classification software BIOCAT, comprises of the Fisher's linear discriminant feature selection method.

Classification

Machine learning and data mining techniques have the ability to accurately and successfully analyze substantial amounts of image data. Many studies have demonstrated the benefits of applying machine learning classification techniques to classify images using features extracted from them. Some of the common classification approaches are SVM, LDA, the K-nearest neighbor (KNN) classifier, ANNs, RF and decision tree classifier, naive Bayes (Abbas *et al.*, 2015). These classification methods for cell nuclei classification normally classify images based on variance in intensities of foreground and background histograms. The classification model performance is subjected to the variances in intensity between image background and foreground. Features such as local Fourier transform, spatial information, shape, and morphological features are normally used for cell nuclei classification (Song *et al.*, 2013).

SVM classifier separates data points of different classes to achieve largest margin between the classes. The SVM classifies the data by finding an optimal hyperplane that is the one with the largest margin between the classes. Margin is defined as the distance from the decision surface to the support vectors (Vapnik and Vapnik, 1998). RF is a nonparametric approach that builds an assembled model of decision trees during the model training. The output is the mode of the individual trees (Breiman, 2001). ANNs are a machine learning method that processes information by adopting the way in which the neurons of human brains work (Daliakopoulos *et al.*, 2005), which consists of a set of nodes that imitate the neuron and carries activation signals of different strength. ANN is a black box as it does not provide any insights on the structure of the function being approximated. There are two approaches to ANN development, which are supervised and unsupervised learning algorithm. The KNN approach comprises of input samples of k -nearest neighbors in the training set in the feature space and assigns the labels of classes that are most similar among its k -nearest neighbors. Performance of KNN is largely reliant on the value of k and the applied distance metric such as Euclidean distances or Manhattan distance. The CART algorithm uses tree structure where the roots are at the top with the leaves at the bottom (Kuhn and Johnson, 2013). A node represents a condition of an attribute, each branch signifies the result of a condition, and each leaf node holds a class label. CART involves three phases: Creation of an initial tree from examples, pruning the tree to remove branches with little statistical validity, and processing the pruned tree to improve its understandability (Alpaydin, 2004; Kotsiantis, 2007). Naive Bayes is a linear classification model that uses Bayes theorem to analyze feature probabilities and assumes feature independence. This approach is particularly useful when the dataset is large and contains many different features.

There is no one particular classification method that is superior and outperforms other available classification methods. Every method has its own advantages and disadvantages. SVM using radial basis function (RBF) classifier is superior in performance and is tolerant to irrelevant and highly correlated features as compared to decision trees, ANN, and KNN classifiers (Alpaydin, 2004; Kotsiantis, 2007).

SVM is suitable when data is not linearly separable. However the SVM algorithm is slower due to the optimization of the hyperplane parameters, the cost parameter C and γ . The selection of these parameters' value involves a grid search. The cost parameter provides an adjustment between training error and model complexity. Higher value of C indicates higher cost for nonseparable samples (Alpaydin, 2004; Kotsiantis, 2007). The SVM model depends on mapping data to a higher dimensional space by using the function of a kernel, the maximum-margin hyperplane will be selected in order to separate training data. Hence SVM improves the accuracy via optimization of the space separation. Thus, it produces a better result compared to the other classification models. ANN and SVM models are considered good at fitting functions and recognizing patterns in various datasets. Both ANN and SVM can approximate practically all types of nonlinear functions (Desai *et al.*, 2008; Gulati *et al.*, 2010). However, there are some limitations such as that standardized coefficients for variables may not be straightforwardly calculated and presented, and it is considered as a "black box" approach. The complete insight into the internal workings of the model or information for evaluating the interaction of inputs is unknown (Dayhoff and DeLeo, 2001). RF compared to ANN and SVM is relatively easier to use and RF provides insight to the variable importance.

Nuclear abnormality is a hallmark of progeria in humans. Analysis of age-dependent nuclear morphological changes in *C. elegans* is of great value to aging research. Classification of *C. elegans* images was made using several machine learning methods such as linear SVM, RF, KNN, ANN, and DT. The data used in this study is imbalanced where the data inhibits unequal amount of data for each class. In order to improve classification performance when imbalanced data set is involved each class is assigned weight based on number of total sample over number of samples in each class. Optimum number of classifiers are identified using the K-fold method and the RF algorithm outperformed all other machine learning algorithms including SVM. The reason behind this is the choice of SVM algorithm in this study, that is, linear SVM. Performance classification of SVM-linear is faster compared to SVM-RBF. However SVM-RBF demonstrates higher classification accuracy and lower misclassification compared to SVM-linear. SVM-linear is a suitable choice for variable selection during iterative training phase and SVM-RBF for all cell types' classification (Abbas *et al.*, 2014; Mao and Tao, 2017). SVM has been used as a classifier to assess the existence of malaria cell *P. falciparum* trophozoites and white blood cells in Giemsa stained thick blood smears. Images were obtained using a smartphone and manually annotated. The results were 80.5% sensitivity for malaria cell and 98.2% sensitivity for white blood cell (Rosado *et al.*, 2016).

Automated plant identification using machine learning methods can be applied to classify plants into appropriate taxonomies. Brilhador *et al.* (2013) compared KNN, ANN, SVM, RF, and naïve Bayes for plant leaf image classification using all features and selected features. SVM outperformed all other classifiers without and with using feature selection method. RF and ANN performance was slightly lower than SVM. Kho *et al.* (2017) applied SVM and ANN classifier for automated ficus leaf identification that resulted in both models having similar performance. K-means method was used for diseased plant leaf image clustering and ANN for classification resulted in accuracy of 94% (Al-Hiary *et al.*, 2011).

Plant leaf identification of 32 different species using convex hull, morphological, color histogram, and distance map features using KNN as classifier achieved an accuracy of 87.3% (Munisami *et al.*, 2015). Automated plant disease using Otsu segmentation method was carried out using four different types of classifiers, that is KNN with k value of 1, ANN, naïve Bayesian, linear SVM, and decision tree. SVM classifier produced the highest accuracy of 94.45% using discrete cosine and wavelet transform and 90% accuracy using texture features alone. Previous studies in plant disease identification (Camargo and Smith, 2009; Al-Hiary *et al.*, 2011) using SVM with texture, shape, histogram of frequency features using thresholding segmentation method, and ANN with K -means clustering using texture features produced a slightly lower classification result of 94% (Akhtar *et al.*, 2013).

In a species identification system successful results have been obtained using ANN and KNN as a classifier. A species identification system using photographic images of fish, plant, and butterfly species uses geometry, morphology, and texture feature and ANN classifier for image recognition. ANN achieved accuracy of about 90% for all species (Hernández-Serna and Jiménez-Segura, 2014). DAISY is a generic species identification system for insect groups using ANN, SVM, and a plastic self-organizing map as classifiers (O'Neill, 2007). ANN and shape features were used to classify the skulls, sex, and region of species of *Suncus murinus*. Skull classification achieved 100% and the other was about 80%. This indicates that shape alone is sufficient for species identification (Abu *et al.*, 2016). KNN was applied to classify the monogenean specimens and achieved classification accuracy of 90% using morphological shape features (Kalafi *et al.*, 2016).

In the medical domain the SVM classifier achieved higher accuracy as well compared to other methods. Comparative study on automated identification of ophthalmic images using local binary pattern and SVM as classifier and wavelet transformation and SVM attained accuracy of 87%. Combination of color and texture feature using SVMs or k NN classifier identification of ophthalmic images can be used for mobile devices application due to ease of implementation and faster processing time (Wang *et al.*, 2017). Early detection of skin cancer melanoma using morphological features of pixel intensity extracted from diseased layer of skin was classified using SVM classifier, which achieved 92% (Li *et al.*, 2013). Identification of tumor location from head and neck MRI images data is vital but very complicated. SVM classifier is used with discrete sine transform and DCT achieve better performance compared to the existing techniques (Gouid *et al.*, 2014). Cervical cell nuclei classification using morphometric and Haralick texture features with PCA for dimension reduction was conducted using linear method, KNN, Mahalanobis, and SVM. SVM classifier with PCA achieved highest classification accuracy (Lorenzo-Ginori *et al.*, 2013).

Application of feature selection and different combination features improves classifier performance in bioimage classification. Feature selection algorithm effect on the performance accuracy of plant leaf classification was studied using KNN, CART, RF, and J48. Gabor texture features and RF feature selection method was used to select significant features in plant leaf identification. RF model outperformed with and without feature selection; meanwhile CART was the worst performing classification model. Classification accuracy increased using selected features compared to using a full set of features for all classification algorithm (Kumar *et al.*, 2015). Adaboost classifiers boosting algorithm for binary classification was used with a combination of shape features using SIFT, color feature using color moment, and texture feature using SFTA in herbal plant identification. Single texture feature and combination of texture and shape feature produced almost similar classification results of 92% compared to using all three features together of 94% or using either shape or color feature alone (Jamil *et al.*, 2015). SVM with RBF kernel classifier using feature reduction method for yeast image classification for 20 classes achieved 87% and classification without feature selection is 95% (Huh *et al.*, 2009).

Deep learning applications have been gaining popularity in bioimage informatics. The deep learning method uses a convolutional neural network (CNN), a special kind of ANN. Individual neurons execute a convolution of a kernel with an input image and generate a filtered output image or a feature map. The input image can be made out of a few channels, and each layer in the neural net holds as many channels of feature maps. The feature maps in the last layer are considered the final features learned by the network and are used for classification. The main difference of CNN from conventional feature based classification methods are features, and the weights of the kernels, are learnt by the CNN algorithm. CNN performance was compared with conventional machine learning classifiers such as SVM, RF, and LDA. CNN outperformed with high accuracy rate of 97%. CNN as a features learning algorithm is as good as conventional features and supervised learning algorithm (Dürr and Sick, 2016). Related literature on CNN application include classification of red blood cells in sickle cell anemia (Xu *et al.*, 2017), breast cancer histopathological image classification (Spanhol *et al.*, 2016), and automatic plant type identification. CNN has been compared with SVM and yielded higher accuracy (Yalcin and Razavi, 2016).

Bioimage software for image analysis and classification uses various classification methods and is easy to use. Area, shape, intensity, texture, and advanced features such as Haralick, Gabor, and Zernike features are the most commonly used features for cell identification in different bioimage software packages (Abbas *et al.*, 2014). CP-CHARM uses LDA as classification and PCA for feature dimension reduction (Uhlmann *et al.*, 2016). WND-CHARM uses thresholding and weighting as feature selection algorithm and weighted nearest neighbor for classification (Orlov *et al.*, 2008). CellProfiler is a Matlab-based package for analysis of biological images using joint boosting classifier limited to two classes of classification (Lamprecht *et al.*, 2007). To enhance CellProfiler capabilities, enhanced CellClassifier (Misselwitz *et al.*, 2010) uses an images analyst by CellProfiler for multiclass classification using SVM. BIOCAT software is used for automatic classification and annotation of 2D and 3D and regions of interest on individual biological images. It is mainly used for cell biology and neuroscience. Feature selection is carried out using Fisher's criterion and supports classifiers such as SVM, KNN, naïve Bayes, DT, and RF (Zhou *et al.*, 2013). FARSIGHT is software comprised of modules of bioimage analysis and classification that uses supervised spectral clustering. CellCognition (Held *et al.*, 2010) uses a hidden Markov model algorithm as classifier. CellXpress is based on SVM and Ilastik (Sommer *et al.*, 2011) uses RF as its classifier. SVM linear and SVM RBF have proven to be superior in classification task compared to joint boosting and LDA classifier. Abbas *et al.* (2014) suggests that the SVM based classifier should be incorporated in bioimage analysis tools' fast and efficient analysis of high-throughput data.

Image Registration and Annotation

Image registration is defined as a process that overlays two or more images from various imaging equipment or sensors taken at different times and angles, or from the same scene to geometrically align the images for analysis (Zitová and Flusser, 2003). Objects taken in different imaging equipment are not alike. Existence of calcification can be identified efficiently by using computed tomography images (CT scan). In MRI uneven intravascular calcification plaque and blood disorders can create image artifacts. Application of using similar image scanning method for example MRI on different scanning equipment with different parameter can also lead to differences in acquired image. The image registration method can be applied to resolve the issues from differences in images acquired due to equipment and parameter settings (Chen *et al.*, 2017).

The basic procedure in the image registration method comprises feature detection, feature alignment from the captured image and the reference image, mapping functions parameter estimation, and image resampling and transformation. Image registration methods are unique to each problem and there is no common technique of image registration that is applicable to all registration tasks due to images' geometric radiometric distortions and noise disturbance, data characteristic, and accuracy threshold level.

Vascular registration of retinal and MRA methods proposed by Chen *et al.* (2017) comprises area and feature based registration methods. The area based method comprises of cross correlation matching and mutual information methods and correspondences estimation from the original image. The feature based method consists of a description of invariance obtained from feature extraction such as correlation coefficient, closed region, geometric features, and coherent point drift. This method proposed by the author can be applied to other tubular structures.

There is a huge amount of images of proteins with cancerous tissues, however due to absence of clear and precise annotations, images from cancerous tissues are not being utilized for developing supervised models for cancer classification (Uhlen *et al.*, 2010). Annotation of biological images has conventionally been done manually by a domain expert and it is very time consuming. Automated annotation *Drosophila* gene expression pattern images and identification of the images have been carried out using the bags-of-words (BoW) method. Images are denoted as BoW based on visual features extracted from the image to produce a visual codebook about the image. Feature of an image based on the regions of an image is extracted using SIFT descriptor for image codebook generation. The spatial BoW method on the FlyExpress image database is used to generate a histogram for each image and frequency of words appearing in an image. The BoW trails the location of visual words appearing on the image. The spatial BoW is an enhancement of the BoW method with spatial properties of an image with better accuracy compared to using nonspatial BoW or nonannotated images (Yuan *et al.*, 2012). Software such as the BIOCAT is used for automated bioimage annotation. The software is able to perform automated image recognition, classification and annotation of images and region of interests with application to cell biology and neuroscience (Zhou *et al.*, 2013).

Closing Remarks

This work discusses general aspects of bioimage informatics covering cell, organism, species, and medical images. Techniques discussed in this work can be applied to various biological images.

Bioimage Databases

Arpah Abu and Sarinder K Dhillon, University of Malaya, Kuala Lumpur, Malaysia

Introduction

In biology, image data can be classified as high-resolution microscopy data, medical imaging data, observed effects in cell, high content screening, molecular imaging and biodiversity (organisms) data. These data are generated via advance experimental and field work as well as from high throughput analysis using the imaging technology. Besides images of organisms, images of protein structures and structural models of proteins and RNA molecules are also available for browsing, querying as well as analysis. Besides the raw source of images obtained, the annotations that describe the related details are valuable source of information. However, till date, very little has been reported in the development of bioimage databases, particularly for storing and pooling the vast amount of scientific image data both at molecular or cellular level. Nevertheless, a substantial amount of work has been done in documenting digital pictures of organisms as in terms of technology it is much simple and affordable.

Generally, bioimage databases are developed for storage and retrieval purposes. The data formats used by these databases are specific to the type of images stored. Retrieval of data from image databases can be done in two ways; the first method accepts only text query to retrieve images (or the content of the database) and the other method accepts image query which referred as content-based image retrieval. In this article, existing work done using both of these approaches are presented. The problems concerning bioimage database are discussed and finally we present a viable solution to develop bioimage databases.

Bioimage Databases Using Text-Based Query

In this section, some of the important and widely used bioimage databases are presented. These databases are text query based, which means the input in the search function is string rather than an image.

Flybase (see “Relevant Websites section”)

FlyBase (McQuilton *et al.*, 2012) is an image database of *Drosophila* genes and genomes. One of the query tools provided in this system is ImageBrowse (see Fig. 1) for browsing the images based on the organ system, life-cycle stages, major tagma, germ layer and all species images.

The images in this database were collected from the researchers' publications such as journal articles and books. The retrieved images are listed in unranked order along with short description (see Fig. 2).

Planetary Biodiversity Inventory – PBI (see “Relevant Websites section”)

The Planetary Biodiversity Inventory – PBI (Gregorev *et al.*, 2003) for Plant Bugs provides a resource about the global plant bug subfamilies Orthotylinae and Phylinae (Insecta: Heteroptera: Miridae) to various users such as systematists, insect ecologists, conservation biologists, the general public, and students via the Internet. In the latest version 6, all users have access to a systematic catalog of plant bug taxa with more than 10,000 species, a digital library of ~30,000 pages, locality database, and updated Methods and News and Outputs. Furthermore, users can view taxon treatments and distribution maps through discoverlife.org by using the search box provided on the page as well as through a dedicated web page, provided in “Relevant Websites section”. Through these portals specimen records are available for approximately 4000 species and more than 250,000 specimens. 56 papers have so far been published with at least 15 additional papers in preparation or in press.

The Plant Bug PBI was made possible with the financial support from the National Science Foundation (NSF) from September 1, 2003 to August 31, 2011.

The images along with taxon information and distribution can be retrieved using Image Database interface in Fig. 3. Users can enter the relevant bug name such as ant, bee and wasp and the retrieved images are listed in unranked order.

Specimen Image Database – SID (see “Relevant Websites section”)

Specimen Image Database – SID (Simon and Vince, 2011) is a searchable database of high-resolution images for phylogenetic and biodiversity research. This database is intended as a reference collection of named specimens and a resource for comparative morphological research. Each image is accompanied by fully searchable annotation, and can be browsed, searched or downloaded. Public users as well can register in this database and the registered users can add, annotate or label the images. Currently, this database is devoted to the insect order Phthiraptera (lice) and contains 7650 images of 440 taxa.

Fig. 1 ImageBrowse in FlyBase.

Key features of SID (see Fig. 4) include web upload/download of images, bulk and single image annotation via web forms, extensive browse and search options by text query, web service facility, web utility to label specific image features, taxonomy served and validated independently by the Glasgow Taxonomy Name Server, alias addresses for images by accession number and freeware which allows anyone to set up the database and serve their own images. The retrieved images are listed in unranked order with the taxon information, host as well as image properties.

Orchidaceae of Central Africa (see “Relevant Websites section”)

Orchidaceae of central Africa (Droissart *et al.*, 2012) is an image database on orchids of Central Africa. It includes scientific names, distribution data, photos, interactive identification keys, web links, and references. The images presented in this database are from intensive fieldwork carried out by the Université Libre de Bruxelles, the Université de Yaoundé I, the Missouri Botanical Garden and the Institut de Recherche pour le Développement in several countries of Central Africa. This information will promote land conservation and sound natural resource management in tropical Africa. The information presented in this database may be suitable for academic, educational, and general purpose.

The database currently comprises information on about 300 illustrated orchid species. The images can be retrieved by using text query based on the taxon name; or browsing the entire database or with few options such as taxa by genus, country or author as shown in Fig. 5. The retrieved images are listed in unranked order with species and authors name.

MonoDb (see “Relevant Websites section”)

MonoDb (Andy and James, 2012) is another biodiversity database that provides image gallery as one of the features in the database. MonoDb is a web-host for the parasite monogenea. As mentioned in this website, the purpose of this website is to help children, adults, experts and non-experts to learn more about this fascinating group of animals. Images in this database can be

Cell Image Library – CIL-CCDB (see “Relevant Websites section”)

CIL-CCDB ([Orloff et al., 2013](#)) is a searchable database and archive of cellular images. As a repository for microscopy data, it accepts all forms of cell imaging from light and electron microscopy, including multi-dimensional images, Z- and time stacks in a broad variety of raw-data formats, as well as movies and animations. A CIL-CCDB was developed as a resource and a tool for the cell biology community such as for researchers, educators and the general public. Images in this database can be retrieved by browsing the entire images provided in the database and by using the simple or advance search features as shown in [Fig. 7](#).

ModBase: Database of Comparative Protein Structure Models (see “Relevant Websites section”)

MODBASE ([Ursula et al., 2014](#)) is a queryable database of annotated protein structure models. The models are derived by ModPipe, an automated modelling pipeline relying on the programs PSI-BLAST and MODELLER. The database also includes the fold assignments and alignments on which the models were based. ModBase was developed by Sali Lab. [Fig. 8](#) shows the main home page of ModBase. The data was organized into datasets in which can be used either available to the public, to the academicians or to specific users.

SWISS-MODEL Repository (see “Relevant Websites section”)

The SWISS-MODEL Repository ([Bienert et al., 2017](#)) as shown in [Fig. 9](#) is a database of annotated 3D protein structure models generated by the SWISS-MODEL homology-modelling pipeline. It was developed by Swiss Institute of Bioinformatics. The aim of

Fig. 3 PBI – Image Database interface.

Fig. 4 SID – Search page interface.

Fig. 5 Orchidaceae of central Africa – Search page interface.

Fig. 6 Monogenean images in MonoDb.

the SWISS-MODEL Repository is to provide access to an up-to-date collection of annotated 3D protein models generated by automated homology modelling for relevant model organisms and experimental structure information for all sequences in UniProtKB. Regular updates ensure that target coverage is complete, that models are built using the most recent sequence and template structure databases, and that improvements in the underlying modelling pipeline are fully utilized. It also allows users to assess the quality of the models using the latest QMEAN results. If a sequence has not been modeled, the user can build models interactively via the SWISS-MODEL workspace.

BOLD SYSTEMS (see “Relevant Websites section”)

BOLD is a cloud-based data storage and analysis platform developed at the Centre for Biodiversity Genomics in Canada. It consists of four main modules, a data portal, an educational portal, a registry of BINs (putative species), and a data collection and analysis

Fig. 11 Rfam searching page.

workbench. The BIN database as shown in [Fig. 10](#) is a searchable database of Barcode Index Numbers (BINs), sequence clusters that closely approximate species. The retrieved images are displayed with their description that give meaning to the images.

Rfam (see “Relevant Websites section”)

The Rfam ([Kalvari et al., 2017](#)) database is a collection of RNA families, each represented by multiple sequence alignments, consensus secondary structures and covariance models (CMs). The Rfam database is curated and maintained at the European Bioinformatics Institute in Cambridge, UK. The resource is collaboration with researchers from Sean Eddy lab at Harvard University, USA. The secondary structures images are retrieved as results with annotated information using a text-based query as shown in [Fig. 11](#).

Bioimage Databases Using Content-Based Image Retrieval

Content-based Image Retrieval (CBIR) is a concept used in image databases. The work presented in Section “Bioimage Databases Using Text-Based Query” are databases with text-based retrieval capabilities. Hence the functionality is limited in the sense that only text query can be used to retrieve images, unlike CBIR database systems, whereby the query input can be an image. Due to the escalation of biological data, new ways have been introduced to store and analyze data. The need of efficient management of the vast visual information has introduced new techniques and tools for content-based image retrieval approach.

[Fig. 12](#) shows a typical architecture of CBIR system depicted from [Torres and Falcao \(2006\)](#). The goal of this approach is to search and retrieve a set of similar images to the user query. The interface layer allows user to send a query image. The images from image database are then assigned as training set images. Both query and training set images features (such as shape, texture and color) are extracted and formed the feature vectors in the feature space. The similarity comparison (such as Euclidean distance and Mahalanobis distance) between the query and training set images are then measured, and the classifier (such as minimum distance, maximum distance and k-nearest classifier) is used to classify the retrieved images. The results are then returned to the user through user interface. As for the results, the retrieved images must be accurate, relevant and related to the user query.

[Rui et al. \(1999\)](#), [Smeulders et al. \(2000\)](#), [Feng et al. \(2003\)](#) and [Torres and Falcao \(2006\)](#) introduced some fundamental techniques as well as technical achievements in the field of CBIR.

As mentioned previously, biologists produce a vast of digital images. From these images, it can be used for identification as well as for teaching and research. [Wang et al. \(2012\)](#) presents a work on butterfly family identification using CBIR, while [Sheikh et al. \(2011\)](#) developed CBIR system for various types of marine life images. A content-based pattern analysis system for a biological specimen collection was developed by [Joyita and Gardner \(2007\)](#) and a CBIR system for fish taxonomy research was also

Fig. 12 A typical architecture of CBIR system.

developed by [Chen et al. \(2005\)](#). As stated in [Wang et al. \(2012\)](#), CBIR is applied because of its capacity for mass processing and operability.

On the other hand, because of the heterogeneous data, complexity of the biology images as well as the images descriptions are often ignored to attach to together with the images, there are few works such as mentioned in [EKEY \(2012\)](#), [Torres et al. \(2004\)](#) and [Murthy et al. \(2009\)](#) to enhance the CBIR capability

The CBIR approach has been applied in medical for teaching, research and diagnostics on diseases. The benefits and future directions have been discussed in [Müller et al. \(2004\)](#). In [Kak and Pavlopoulou \(2002\)](#), CBIR is used to automate retrieval from large medical image databases and presented solutions to some of them in the specific context of HRCT images of lung and liver. [Scott and Chi-Ren \(2007\)](#) presents a knowledge-driven multidimensional indexing structure for biomedical media database retrieval. While in [El-Naqa et al. \(2004\)](#) and [Rosa et al. \(2008\)](#), they use CBIR approach for digital mammographic masses. As to improve the retrieval efficiency, some of the works such as mentioned in [Demner-Fushman et al. \(2009\)](#), [Hsu et al. \(2009\)](#) and [You et al. \(2011\)](#), they have combining the metadata approach into CBIR approach.

The CBIR approach has been used as well in several applications such as face identification, digital libraries, historical research, medical and geology. It is probably the most useful application in biology. In this article, some of these applications are presented as in this section, focusing on medical and biology applications.

Google Image Search (see “Relevant Websites section”)

Google Image Search is a Google’s CBIR system. Query specification follows the query by example using external images. However, it does not work on all images. Metadata query function is also provided.

Fig. 13 Chemical structure search using CBIR in BioSilico.

Macroglossa Visual Search (see “Relevant Websites section”)

Macroglossa is a visual search engine based on the comparison of images, coming from an Italian Group. For image retrieval, query specification follows the query by example using external images or query by category such animals, biological, panoramic, artistic or botanical. Macroglossa supports all popular image extensions such jpeg, png, bmp, gif and video formats such avi, mov, mp4, m4v, 3gp, wmv, mpeg.

BioSilico (see “Relevant Websites section”)

BioSilico is a web-based database system that facilitates the search and analysis of metabolic pathways. Heterogeneous metabolic databases including LIGAND, ENZYME, EcoCyc and MetaCyc are integrated in a systematic way, thereby allowing users to efficiently retrieve the relevant information on enzymes, biochemical compounds and reactions. In addition, it provides well-designed view pages for more detailed summary information as shown in [Fig. 13](#).

CATH (see “Relevant Websites section”)

The CATH ([Sillitoe et al., 2015](#)) database is a free, publicly available online resource that provides information on the evolutionary relationships of protein domains. It was created in the mid-1990s by Professor Christine Orengo and colleagues, and continues to be developed by the Orengo group at University College London. The CATH database is a hierarchical domain classification of protein structures in the Protein Data Bank. Protein structures are classified using a combination of automated and manual procedures. There are four major levels in this hierarchy which are Class, Architecture, Topology, and Homologous superfamily. For any given structure classified in the database, CATH gives you information on the structure and function of that protein. The evolutionary relationships involving the structure of interest and other proteins in the database can also be determined. These tasks can be performed by searching using Text or ID, Sequence or Structure in PDB image format as shown in [Fig. 14](#).

IDR – Image Data Resource (see “Relevant Websites section”)

IDR ([Williams et al., 2017](#)) is online, public data repository seeks to store, integrate and serve image datasets from published scientific studies. It was developed by University of Dundee & Open Microscopy Environment. IDR allow the community to search, view, mine and even process and analyze large, complex, multidimensional life sciences image data as shown in [Fig. 15](#). Sharing data promotes the validation of experimental methods and scientific conclusions, the comparison with new data obtained by the global scientific community and enables data reuse by developers of new analysis and processing tools.

Fig. 14 CATH image database using image query.

Fig. 15 Retrieved images from fungi dataset.

BioDIG (see “Relevant Websites section”)

BioDIG (Oberlin *et al.*, 2013) is a generic set of tools that allows linking of image data to genomic data. BioDIG features the following: rapid construction of web-based workbenches, community-based annotation, user management and web services. By using BioDIG to create websites, researchers and curators can rapidly annotate a large number of images with genomic information. The BioDIG includes an image module, a genome module and a user management module as shown in Fig. 16.

RNA 3D Motif Atlas (see “Relevant Websites section”)

RNA 3D Motif Atlas (Petrov *et al.*, 2013) is a comprehensive and representative collection of internal and hairpin loop RNA 3D motifs extracted from the Representative Sets of RNA 3D structures. It was developed by BGSU RNA Structural Bioinformatics at

Fig. 16 The *Mycoplasma pneumonia* image annotated with genome data in BioDIG interface.

Bowling Green State University. The 3D images of RNA motif are retrieved using browsing featured motifs which are Kink-turn (as shown in Fig. 17), C-loop, Sarcin, Triple sheared, Double sheared T-loop, and GNRA.

Discussion on Bioimage Databases

Many issues have been discussed and suggested (Rui *et al.*, 1999; Smeulders *et al.*, 2000; Shandilya and Singhai, 2010) to improve the typical Content-based Image Retrieval (CBIR) based image databases such as involve user interaction, integration of multi-disciplines approach, relevance feedback and reducing semantic gap. The main purpose of these improvements is to enhance the efficiency of image retrieval.

Most previous works focused on image representation (Krishnapuram *et al.*, 2004; Wei *et al.*, 2006; Lamard *et al.*, 2007; Sergyan, 2008), classifier algorithm (Xin and Jin, 2004; Duan *et al.*, 2005; Liu *et al.*, 2008), the use of image database (Kak and Pavlopoulou, 2002), and relevance feedback (Stejić *et al.*, 2003; Zhang *et al.*, 2003; Ortega-Binderberger and Mehrotra, 2004;

Fig. 17 Retrieved RNA 3D motifs using Kink-turn featured motif.

Wang and Ma, 2005; Wei and Li, 2006) to enhance the CBIR system. However, as mentioned in Liu *et al.* (2007), research focus has been shifted into reducing the semantic gap and identified five major categories of the state-of-the-art techniques in narrowing down the semantic gap i.e., (i) using object ontology to define high-level concepts; (ii) using machine learning methods to associate low-level features with query concepts; (iii) using relevance feedback to learn users' intention; (iv) generating semantic template to support high-level image retrieval; (v) fusing the evidences from HTML text and the visual content of images for WWW image retrieval.

On the other hand, as stated in Torres *et al.* (2004), the implementation of CBIR systems raises several research challenges such as (i) new tool for annotating needs to be developed to deal with the semantic gap presented in images and their textual descriptions; (ii) automatic tool for extracting semantic features from images; (iii) development of new data fusion algorithm to support text-based and content-based retrieval when combining information of different heterogeneous formats; (iv) text mining techniques to be combined with content-based descriptions; and (v) investigating user interfaces for annotating, browsing and searching based on image content.

Related works focusing on reducing the semantic gap between the visual (low-level) features and the richness of human semantic (high-level features) is in progress. Lin *et al.* (2007) proposes the integration of textual and visual information for cross-language image retrieval; Zhang *et al.* (2011) presents automatic image tagging automatically assigns image with semantic keyword called tag, which significantly facilitates image search and organization; Aye and Thein (2012) presents a retrieval framework can support various types of queries and can accept multimedia examples and metadata-based document; and Lee and Wang (2012) presents a utilization of text- and photo- types of location information with a novel approach of information fusion that exploit effective image annotation and location based text-mining approaches to enhance identification of geographic location and spatial cognition.

Generally, there are two approaches to image retrieval which are textual-based that retrieves images based on human-annotated metadata, and content-based that analyzes the actual image data (Avril, 2005). Many digital libraries have annotation capabilities for image digital libraries such as Imense Image Search Portal (imense, 2007), Incogna Image Search (Incogna, 2012), and Anaktisi (Chatzichristofis *et al.*, 2010). Yet, in biology, very few are providing the capabilities to integrate text- and content-based annotation and retrieval of parts of images such as EKEY (EKEY, 2012), SuperIDR (Murthy *et al.*, 2009), and teaching tool for parasitology (Kozievitch *et al.*, 2010). EKEY is a web-based system that provides taxonomic classification, dichotomous key, text-based search and combination of shape and text-based search which taking into account fish shape outlines and textual terms. For the SuperIDR, instead of provides same features as EKEY, it enables the user interaction to add content, support for working with specific parts of images, performing content-based image annotation and retrieval and has pen-input capabilities which mimicking free-hand drawing and writing on paper. While in terms of database system, the relational database architecture was used for text annotation. Both systems are used in the Ichthyology domain. As an alternative approach to teach, compare and learn concept about parasites in general, research group in Kozievitch *et al.* (2010) adapted SuperIDR.

Fig. 18 The Model procedural flow.

To summarize, based on the review done, several main points are derived:-

- (1) Most of the image databases provide only text query option to retrieve the images from the database.
- (2) None of the existing systems uses ontology-based image annotation and retrieval to perform image pre-classification. The nearest are the EKEY and SuperIDR whereby each image is annotated with certain parameters such as species name. Thus, the user can customize their search according to these parameters to find the nearest match to the query image.
- (3) Biology data is heterogeneous, containing complex images and terminology to describe the data is always evolving overtime. Thus, graph data is suitable approach for text data modelling.
- (4) Both text- and content-based image retrieval approaches have their own advantages. Yet both approaches as well have a same limitation, which is, may retrieve irrelevant images.

Finally, in order to improve the efficiency of image retrieval in CBIR approach, one of the solutions to reduce the semantic gap limitation is by combining text-based image retrieval into CBIR. By using this approach, it will narrow down the most relevant images to be used for training set images. There are few aspects that are important to consider when developing the integrating text- and content-based image retrieval model, i.e., textual data representation, image annotations, query specification and the expected output of the retrieval process.

Suitable and proper vocabularies are needed in order to annotate the image because the images will be retrieved based on the vocabularies. The annotated data is required to represent in meaningful, dynamic and flexible manner so that any inclusion new vocabulary in future will be able to accommodate without changing the whole data structure. As for query specification, both textual and image query are needed. The last aspect is the output of the retrieval process, which is crucial in determining whether the retrieval process works well and in an efficient manner. Thus, to achieve this, the most relevance images must be retrieved with their annotation.

Proposed Solution for Bioimage Databases Using Ontology and CBIR Approaches

The details of the proposed solution in relation to the identified problems are presented here. The proposed solution aims to integrated both textual and image retrieval from image databases. The proposed image retrieval using ontology and CBIR approaches is shown in [Fig. 18](#). This architecture is proposed by [Arpah et al. \(2013\)](#).

In this model, the Ontology Based Information Retrieval (OBIR) layer determines the training set for Content Based Image Retrieval (CBIR). Ontology-based image retrieval is used as technique to reduce the training images for the CBIR layer by eliminating the irrelevant images using the text-based query in OBIR layer. This technique is also referred as data reduction usually used in data pre-processing to obtain a reduced representation of the dataset, which is smaller in quantity, yet closely maintains the integrity of the original data.

Conclusion

In this article, bioimage databases are presented in two classified categories which are text-based retrieval and image-based retrieval or more commonly known as content-based image retrieval. Based on the reviews presented in this article, we conclude that bioimage databases have not been able to completely harness the power of computer vision and image analytics in building the data archives. As such, a substantial amount of work in this field is required to build scientific databases, using ontologies for text queries and content based image retrieval methods for image queries. The methodology presented by [Arpah et al. \(2013\)](#) and the initiative started by [Williams et al. \(2017\)](#) are good example of research to be modeled in building bioimage databases. Finally, for the advancement of science, particularly biology, access to a wide range of image data is necessary to conduct transformative research.

Introduction

Bioimage is a combination of the two words “Biology” and “image”. Biology means the study of life and living organisms, including their physical and chemical structure, function, development and evolution ([Murphy and Davidson, 2001](#)) and thus, Bioimages broadly imply biologically related images. These images can be taken from large varieties of organisms of any size, ranging from whole organisms down to a single molecule level. There are many techniques to obtain these images, that can be categorized according to sizes into three levels, namely molecular, microscopic and whole organism levels. First, images from the molecular level include scanning or transmission electron microscopy ([Tsien, 2003](#)). For the microscopic level, Bioimages include those from confocal or two-photon laser scanning microscopy ([Tsien, 2003](#)). The last category is composed of those Bioimages of parts or organs of organisms, obtained from X-ray, magnetic resonance, ultrasound, endoscopy, thermography, positron emission tomography (PET), Single-photon emission computed tomography (SPECT) and inferred ([Jia et al., 2016](#)) and others. These Bioimages require domain expert visual instruction to interpret them. However, these manual interpretation steps are very tedious, error prone and time consuming. To overcome the limitation, the use of computer-aided systems such as image processing techniques, has been introduced. Thus, components/objects from Bioimages must be automatically extracted and converted into a format that any image-analysis algorithm can efficiently processed.

Bioimage Segmentation: Definition and Challenges?

Humans understand and identify specific parts of an image because of our recognition through memorization and retrieval of said information. To be able to do this using computer, automatic identification of useful components in an image is needed. Image segmentation is a process to partition an image into objects, which can be either meaningful or non-meaningful and therefore, it is a vital process to identify objects of interest. Bioimage segmentation plays an important role in many branches of life sciences such as, biotechnology, precision agricultures, pharmacology, advanced medicine and microbiology. These domains require large number of images to be processed. For more efficiency and automation, computer-based systems are required to identify objects or region of interest before passing them to other stages of image processing, such as feature extraction, image classification and image recognition ([Gonzalez and Woods, 2008](#)). Even though research on image segmentation has been conducted for more than 40 years ([Zhang, 2009](#)), there are no single solution for all kinds of images. Such a challenge majorly stems from a wide spectrum of image qualities. For example, in microscopic image analysis, the difficulties in segmentation are from inconsistent stained color, over-exposed or under-exposed to microscope light, poor contrast, varieties of cell types, cell overlapping and unwanted objects (artifacts) in the image ([Win and Choomchuay, 2017](#)). Another example of confounding signals is found in an analysis of intravascular ultrasound images whose poor qualities come from the presence of calcifications, shadows, transducer reflection, speckle noises and bifurcations and intensity-variant of structure ([Jodas et al., 2003](#)). Customized segmentation algorithms are yet to be devised for some specific problems ([Gupta et al., 2017](#)).

Segmentation Techniques: Review

In image analysis, the segmentation step is carried out after some pre-processing processes such as noise reduction, color conversion and enhancement processes to suppress unwilling distortions, transform data or enhance features for further processing. Segmentation techniques can be further classified into seven classes based on their methodologies ([Fig. 1](#)), including thresholding segmentation, region-based segmentation, edge-based segmentation, contour-based segmentation, clustering-based segmentation, recognition-based segmentation and computational intelligence-based segmentation ([Patil and Deore, 2013](#); [Kaur and Kaur, 2014](#); [Anjna and Kaur, 2017](#)). The underlying theoretical foundations and limitations of the methods in these classes are discussed in the following subsections.

Thresholding Segmentation

Segmentation algorithms from this class share a common scheme that is using a pixel intensity as a threshold to partition an image into two partitions. For any pixel p located at a coordinate (x,y) , the pixel p is assigned to one partition if its intensity I , at the coordinate (x,y) is greater than or equal to the threshold value Th , i.e., $I(x,y) \geq Th$. Otherwise the pixel is assigned to the other partition ([Kaur and Kaur, 2014](#)). The performance of this kind of thresholding protocol relies on its threshold value, which can be determined manually or automatically.

Fig. 1 Seven main classes of segmentation methods, that are classified based upon their core techniques used to partition input images: (1) thresholding, (2) region-based, (3) edge-based, (4) contour-based, (5) clustering-based, (6) recognition-based, and (7) computational intelligence-based classes.

The automatic thresholding techniques may be further divided into six sub-categories based on distinguishable characteristic at the pixel level such as histogram shape information, measurement space clustering, histogram entropy information, image attribute information, spatial information and local characteristics (Zhang, 2001). The first category uses the information of histogram shape such as peaks, valleys and curvature for thresholding. Examples of shape thresholding are Otsu, Convex hull thresholding, Peak-and-valley thresholding, Shape-modeling thresholding and others (Sezgin and Sankur, 2004). The main idea of the Otsu method, named after the inventor, Otsu (1979) is to find an optimum threshold for separating an image into two classes (object and background). This Otsu technique operates by iterating over all possible threshold values and selects the threshold that minimizes their intra-class variances or maximizes their inter-class variances. For the second sub-category, measurement of space clustering, the number of clusters is always set to two, namely the object cluster and the background cluster. The thresholding value, also called the discriminator, is used to create a mask (0 or 1 corresponding to each pixel from the original image) that can separate objects from the background. Examples of the measurement of space clustering category include Iterative thresholding, Clustering thresholding, Minimum error thresholding (Sezgin and Sankur, 2004). The entropy-based thresholding sub-category utilizes the concept of the average level of information, known as the entropy as a criteria to look for the most suitable thresholding value that best preserves the information containing in the original image. A method, called maximum entropy thresholding, was introduced by Kapur *et al.* (1985). In their approach, the threshold is selected if the sum of entropies of the object and the background reaches the maximum value. Another example of entropy-based is the cross-entropy technique (Kapur *et al.*, 1985) when the threshold value is selected by minimizing the information difference between the input and output images. Object attribute-based segmentation algorithms commonly employ similarity of attributes such as shape compactness, gray-level moments and texture between input and output images (Tsai, 1985; Pal and Rosenfeld, 1988). Thresholding methods, belonging to the spatial sub-category, uses higher-order probability distribution of gray value of pixel and its neighborhood such as context probabilities, correlation functions and co-occurrence probabilities (Cheng and Chen, 1999). Finally, those local characteristic segmentation algorithms make use of local statistics like range and variance of range and variance of a pixel and those from other pixels around it. More examples of the segmentation techniques based on thresholding are presented in Sezgin and Sankur (2004).

The above thresholding-based image segmentation techniques are computationally fast and very easy to implement. They are commonly adopted and implemented by many real-time applications (Dass *et al.*, 2012; Anjna and Kaur, 2017; Patil and Deore, 2013). However, these simple segmentation techniques are not good when processing images that have uneven illumination background with broad and flat valleys. Using a threshold to segment poor images with high degree of noise interferences results in poor segmentation outputs. Furthermore, these algorithms do not offer spatial characteristic of image. To demonstrate, how thresholding-based segmentation performs, Fiji (Schindelin *et al.*, 2012), which is a nice image processing software that bundles all popular image processing algorithms in ImageJ (Schneider *et al.*, 2012) was used. To segment an MRI image using thresholding

Fig. 2 An example of a brain Magnetic Resonance Imaging (MRI) image. (a) The original MRI scanned image and (b) the segmented image with a threshold set to 30, where regions highlighted in red represent detected background.

(Fig. 2), choose Fiji: image → adjust → threshold from the main menu. A pop-up window displaying the histogram profile of the selected image will be shown where the user can adjust the thresholding parameter using a slide bar.

Edge-Based Segmentation

Edge-based segmentation methods detect “discontinuity” properties such as gray change, color distinctness and texture variety that can demarcate between different regions. Particularly, edges and region boundaries are closely related because lines around an object create region boundaries. This kind of edge detection scheme is commonly used as a pre-processing step to enhance other segmentation techniques. There are different types of edges that are considered in algorithms from this edge-based segmentation class, namely ramp edge (gradually change in intensity), step edge (an abrupt change in intensity), roof edge (not instantaneous over a short distance) and spike edge (a quick change in intensity values) (Anjna and Kaur, 2017). Krishnan *et al.* (2017) classified edge-based segmentation according to three operators used to detect the changes: classical operator, Laplacian of Gaussian operator and optimal operator. A classical operator is the first order derivation with examples such as Sobel operator (Gonzalez and Woods, 2008), Prewitt operator (Prewitt, 1970), Robert’s cross operator (Bansal *et al.*, 2012), Kirsch edge detection (Kirsch, 1971) etc. Laplacian of Gaussian operator uses to find the second derivation. Finally the optimal operator uses a multi-stage algorithm to detect a wide range of edge information, e.g., Canny edge detection (Canny, 1986). Fig. 3 shows a resulting segmented fingerprint image (right panel) using ImageJ by choosing ImageJ: Plugins → Canny Edge Detector from ImageJ menu.

Edge-based methods are simple to implement and yield good results in most cases. However, for those images which contain too much noises too many traces, resulting edges identified by an edge detection method are usually discontinued and very fragmented. Therefore an edge linking algorithm to join these fragments and construct separable boundaries is needed.

Region-Based Segmentation

Region-based segmentation methods partition an image using a concept of region similarity which must be predefined. To form a region, a picture element (pixel) that is an elementary building block for bitmap (raster) images (Kaur and Kaur, 2014) is compared to the neighboring pixels. If the similarity criteria is met, these pixels will incrementally be formed as a region. These region-based segmentation methods can be categorized into two groups, (1) region growing group and (2) region splitting and merging group (Kaur and Kaur, 2014). The region growing group incrementally expands a boundary of a region by merging those similar pixels together. Examples of algorithms from the region growing group include Seeded Region Growing, Theoretical Criteria, and Multistep Region Growing (Vantaram and Saber, 2012). A recent review by Adamu and Ding (2015) further classifies these region growing segmentation techniques into Seeded Region Growing (SRG) and Unseeded Region Growing (UsRG). For SRG, the growing process defines seed points or seed pixels whose properties can be used as inclusion criteria for expanding a region. The neighboring pixels that satisfy the inclusion criteria join the existing seed pixels. This inclusion selection is done iteratively until all pixels are examined. Clearly, segmentation results from the SRG algorithms are very much subjective and dependent upon the selected seeds. Unlike the SRG protocol, UsRG techniques do not require preselected explicit seeds. UsRG algorithms arbitrarily define one single region covering some pixels that will be used to grow the region boundary iteratively by recruiting more neighboring pixels. When encountering a pixel whose property greatly differs from the current growing region, that pixel will start a new region, which in turn start growing accordingly.

Fig. 3 A fingerprint image contains mostly traces of fingerprints presenting a challenge in segmentation based on classical edge-detection since detected edges may not be connected to form good boundaries for partitioning. (a) The original fingerprint image and (b) The segmented image using Canny edge detection, where contour traces show potential edges extracted from the original fingerprint.

Fig. 4 Using Watershed to partition a clear region boundary image of a ladybug produces over-segmented result: (a) The original image of a ladybug and (b) the over-segmented result after using Watershed.

For the region splitting and merging class, algorithms in this class use divide-and-conquer to recursively partition (split) the whole image and then quickly merge those small yet similar regions to create bigger regions. In (Gorte, 1996), the quadtree segmentation algorithm was used by setting the whole image as a root of the quadtree. The splitting commences if all pixels in this whole image are not homogeneous. The splitting process create four child squares, each of which is carried out recursively using the aforementioned splitting procedure. Splitting terminate if all the pixels in the region are homogeneous (being sufficiently similar according to the criterion) or having only one pixel in it. The merging of similar regions grows from the leaves of this quadtree toward the root. As an example, Watershed is an efficient region-based splitting method (Courprie and Bertrand, 1997). The term “Watershed” refers to a geological watershed, which separates adjacent drainage basins. An input image is treated like a topographic map, whose pixels’ brightness represent the heights of ridges. Examples of Watershed-based algorithms used to partition regions are watershed by flooding, watershed by topographic distance, watershed by the drop of water principle, inter-pixel watershed and topological watershed (Courprie and Bertrand, 1997).

Advantages of region-based methods are having high robustness, preserving the boundary of the segmented regions, producing coherent regions (regions with high degree of pixel uniformity). Nevertheless, objects with multiple disconnected regions present greater challenges, requiring human intervention for selecting input seed pixels. Furthermore, the resulting segmentations by the region-based methods are highly dependent on the choice of input seeds for seeded region growing. Watershed-based methods are likely to produce over-segmented results. As an example, Fig. 4 presents a ladybug image with Watershed-based segmentation algorithm, provided in Fiji to partition the image. To operate this, from Fiji main menu choose: Fiji: Plugins → MorphoLibJ → Segmentation → Classic Watershed. The resulting image displays too many regions that Watershed attempted to segment.

Fig. 5 A CT scan image does not have explicit edge to be detected (a). Using contour-based segmentation, important objects in this image can be detected as shown in the right panel (b).

Contour-Based Segmentation

A contour-based method is used for tracking boundaries (boundary tracing) in an image. First, a closed region (closed contour line) is designated as the starting boundary. This starting boundary is iteratively modified by either shrink/expansion operations; thus this changing boundary is also called an active contour. There are two types of active contour models, (1) the parametric active contour model such as Balloon Snake, Distance Snake and Gradient Vector Flow Snake and (2) the geometric active contour model such as level sets, coupled level-set, pseudo level-set etc. (Baswaraj *et al.*, 2012; Vantaram and Saber, 2012). Particularly, Snake (Kass *et al.*, 1988) moves a contour based on an energy minimization while level-set (Osher and Sethian, 1988) moves a contour according to a level of a function. A contour changes its location and shape based on “a predefined force function” that pulls the contours toward features of interest. In Snake, a set of snake points must be selected from an image. Those snake points will be moved to the next location by determining the local minimum energy until the points stop at the object boundary. In Level set, the algorithm partitions several objects in an image by implicit curve propagation. The curve is moved as the evolution of the level set function. This method helps estimate the geometric properties of the evolution structure (Bhaidasna and Mehta, 2013). Dynamic contour concept provides a clever way to detect objects from the input image with continuous boundaries, stability and irrelevancy with topology. A good segmentation relies on the initial locations (snake points) and having only one object in the image. Fig. 5 presents a CT scan image that does not have clear boundaries. By applying level-set from Fiji by choosing: Plugins → Segmentation → Level Sets. Significant objects can be detected by means of contour-based segmentation.

Clustering-Based Segmentation

Clustering is a method to group data into clusters based on their similarities (Dehariya *et al.*, 2010). The idea of clustering-based segmentation methods is to segment an image by assigning pixels with similar characteristics to a k number of groups (clusters) when k is given (Sharma and Suji, 2016). A membership function is used to define if a pixel belongs to the cluster. Such a function is described using a membership matrix with numbers between 0 and 1 representing a degree of membership of a pixel to a cluster. The pixel assignment continues until the maximum separation between clusters exceeds a given threshold.

There are two main types of clustering, (1) hard clustering such as Voronoi Tessellation, Centroidal Voronoi Tessellation, K-Mean clustering, Mean shift clustering, and Adaptive clustering (Vantaram and Saber, 2012) and (2) soft clustering such as Fuzzy-C-Mean (Kaur and Kaur, 2014). Hard clustering partitions an image into a given number of clusters with a restricted constraint that only one pixel belongs to one cluster. In this case, the hard clustering membership functions with the entry value of either 1 or 0 representing a membership status (being a member or not). K-Means clustering is a well-known hard clustering technique that first estimates a center for each of the K clusters, then each pixel will be assigned to those K clusters based on a similarity criterion such as distance, connectivity, intensity between pixel and cluster. The pixel assignment process attempts to minimize the inter-cluster similarity (between different clusters) and maximizing the intra-cluster similarity (within the group). Unlike hard clustering, soft clustering makes use of a flexible membership function and allows a pixel to be assigned to more than one cluster with varying degrees of membership ranging from 0 to 1. This type of flexibility is more natural than that of hard clustering. The Fuzzy-C-Mean algorithm (FCM) belongs to the soft clustering class (Christ and Parvathi, 2011). FCM is more flexible but its computational time could be expensive. The computational time of FCM can be dramatically reduced by means of using an intensity histogram of an image instead of accessing at the pixel level (Kaur and Kaur, 2014).

In summary, these clustering-based segmentation algorithms are quite robust to use in most images. However, all clustering-based segmentation methods require a predefined number of clusters. Most clustering techniques are largely sensitive to noises and other image artifacts that could interfere with the clustering assignment. Fig. 6 presents a segmentation result of a flower image

Fig. 6 K-mean clustering-based segmentation algorithm was used to detect different flowers. (a) A flower image with big (yellow) and small (white) flowers with leaves among them (b) the segmented image where both type of flowers are clearly separated.

that use K-mean clustering when $K=4$ to identify these flowers. The analysis was performed using ImageJ: Plugins → Segmentation → k-means Clustering.

Recognition-Based Segmentation

The aforementioned image segmentation techniques segment an image by grouping pixels that have something in common, like common colors, textures, intensities etc. Once the image is segmented using these techniques, a whole object or region may be oversegmented. Thus these segmented regions must be combined so that true objects can finally be extracted. The process of using fundamental image segmentation to identify uniquely primitive regions and then merge them to form the objects and background is called the bottom-up method. Bottom-up is quite useful for most images and generally produce good segmentation results; however, there are some complex images containing objects that cannot be well partitioned/detected by the former segmentation algorithms. For example, a segmentation algorithm may partition background from real object(s) but toward the final step, similar colors/textures of background and the objects may be merged. This happens because of the lack of meaningful information about the objects of interest. Human utilizes knowledge about each object in order to differentiate an object from the background or other objects. Top-down image segmentation (Borenstein and Ullman, 2002) imitates human recognition process by including a matching model to do the job by utilizing some characteristics of objects with known shapes to guide its segmentation process.

Another variant of image segmentation algorithm is the combination of both bottom-up and top-down approach (Ferrari *et al.*, 2006; Wang *et al.*, 2007; Levin and Weiss, 2009). The approach by Wang *et al.* presents an algorithm that combines both top-down recognition and bottom-up image segmentation. It consists of two steps, (1) hypothesis generation and (2) verification. In the first step, a set of object locations and figure-ground masks, called hypotheses, are constructed. Then the verification step uses these object hypotheses to compute a set of feasible segmented objects where the false positive objects are subject to be eliminated using False Positive Pruning (FPP) (Wang *et al.*, 2007). Advantages of these recognition-based segmentation algorithms include the unique ability to handle images with extensive clutter of objects, dominant occlusion, and large scale and viewpoint changes (Levin and Weiss, 2009). In particular, these algorithms can be used to track an object in an image so that no matter how the original image rotates or even shifted, the object will always be recognized. Fig. 7 shows how a red flower with a specific shape and color is tracked using a recognition-based segmentation algorithm from Fiji. From the main menu of Fiji: Plugins → Feature Extraction → Extract SIFT Correspondences.

Computational Intelligence-Based Segmentation

Human vision can efficiently recognize or identify an object from its background even if the object is not clearly or completely standing out. Clearly, gathering and using primitive information from an image to help partition is not enough. To improve this computational processing, researchers employ computational intelligence including Neural Network and other nature-inspired algorithms. Examples of Neural Network are Conventional Neural Network, Concurrent Neural Network, Deep Learning (Zheng *et al.*, 2015). The Deep Neural Networks was adopted to help detect brain tumor of various shapes, sizes and contrasts from magnetic resonance images (Havaei *et al.*, 2017). The adoption of Deep Neural Network in image segmentation creates a novel Convolutional Neural Networks (CNN) architecture that concurrently utilizes both local and global contextual features. Nature-inspired algorithms efficiently identify the best solution from a large number of finite solutions by mimicing how nature solves a combinatorial optimization problem and comes up with a good solution. Examples of these nature-inspired optimization algorithms include swarm intelligence, ant colony optimization (ACO), bird flocking, bacterial growth, bee colony, fish schooling, cuckoo search and others (Passino, 2002; Sharma *et al.*, 2015). A recent nature-inspired segmentation algorithm is the combination of ACO and genetic algorithm (Rahebi *et al.*, 2010). This work by Rahebi *et al.* is a probabilistic technique mimicking ant foraging behavior to choose an

Fig. 7 An image with many red flowers scattered and buried in the background. To track a particular object (a flower in a small window in the left panel), a recognition-based segmentation technique is used to perform the task.

optimal path by following ant pheromone to bring food back to their nest quickly. ACO segmentation models an image as a graph where nodes represent pixels. The algorithm generates artificial ants to store pixel intensities and construct a pheromone matrix that keeps track of paths (graph edges) that ants often visit. Nature-inspired algorithms can detect meaningful objects that may be incomplete or partly overlapped with other background. However, these algorithms can be very time consuming as learning stage is required to provide sufficient intelligence to these algorithms. [Fig. 8](#) presents an image containing different fishes. Using “Trainable Weka Segmentation” in Fiji: Plugins → Segmentation → Trainable Weka Segmentation, fishes can be detected.

Segmentation Techniques: Case study

In order to demonstrate the basic idea of each technique, a Giemsa-stained blood smear image with varying image conditions, namely in-focus, with noise and with uneven illumination, are used ([Fig. 9](#)). This blood smear image ([Fig. 9\(a\)](#)) was obtained from [Kaewkamnerd et al. \(2012\)](#) containing white blood cells (big black dots) and malaria parasites (small dots). Random noises, dots whose sizes are smaller than those of malaria parasite in the original image, were added to the original image ([Fig. 9\(b\)](#)). Finally the illumination scale is adjusted so that the image has illumination gradient ([Fig. 9\(c\)](#)). These three images are used as inputs for different segmentation algorithms. The image processing tool, named Fiji, is used for comparison purposes.

Thresholding-Based Method

Thresholding segmentation in Fiji was used to process the above three images in [Fig. 9](#). Thresholding is able to segment all of the white blood cells (marked by blue region around each cell) as well as most of malaria parasites ([Fig. 10\(a\)](#)). With the present of noises, the segmentation result ([Fig. 10\(b\)](#)) reveals that only few malaria parasites are identified; random noises clearly interfere with thresholding segmentation. When illumination is uneven, thresholding segmentation could neither detect both white blood cells nor malaria parasites in the area affected with dark illumination. Particularly, the whole area with dark illumination was partitioned into one big object region (blue shaded area in [Fig. 10\(c\)](#)).

Edge-Based Method

For edge-based segmentation, the Canny edge-based method in Fiji was used. Similar to thresholding, Canny was able to segment the original in-focus blood smear image ([Fig. 11\(a\)](#)). For the noisy image, Canny identified more objects ([Fig. 11\(b\)](#)), via its edge detection scheme, than that from in-focus original image ([Fig. 11\(a\)](#)) as well as from the uneven illumination image ([Fig. 11\(c\)](#)). Noises introduce discontinuities of pixel intensity that provide suitable environment for edge-based segmentation to make a decision. However, most objects detected by Canny are not connected, causing difficulties to further post-process this image.

Fig. 8 An aquarium image has different kinds of fishes that may blend in with the blue background (a), presenting a challenge in image segmentation. Using a computational intelligence, fish objects can be detected (b).

Fig. 9 Test Images (a) In-focus image. (b) Image with noises. (c) Image with uneven illumination.

Region-Based Method

The Watershed region-based method in Fiji was used to perform segmentation on the blood smear images in Fig. 9. However, Watershed over-segmented all of the three input images. Fig. 12(a) shows that the segmentation of white blood cells includes some of the malaria parasites around them. The light gray area of the background was clearly over-segmented. Such over-segmented effects appear more in the noisy image (Fig. 12(b)) which might have been influenced by those small noisy dots added to the original image. Fig. 12(c) also reveal the over-segmented result on uneven illumination blood smear image. Watershed is still over sensitive to changes of pixel illumination.

Fig. 10 Result images using thresholding method (a) In-focus image. (b) Image with noise. (c) Image with uneven illumination.

Contour-Based Method

In this experiment, the Level-set contour-based segmentation was used. To demonstrate the region growing in Level-set, we assigned the initial seeds to the centers of those white blood cells in three images. Level set was able to correctly detect boundaries of all white blood cells from the original blood smear image ([Fig. 13\(a\)](#)). However, those noisy dots affect the performance of the region growing process ([Fig. 13\(b\)](#)) where fewer white blood cells were correctly traced. Uneven illumination did not interfere with the object detection ([Fig. 13\(c\)](#)).

Clustering-Based Method

K-Mean clustering in ImageJ was used in this experiment. K-Mean clustering identifies regions in the in-focus image into two clusters ($K=2$), namely white blood cells and malaria parasites. All white blood cells are identified while only some of malaria

(a)

(b)

(c)

Fig. 11 Result images using Canny edge-based method (a) In-focus image. (b) Image with noise.(c) Image with uneven illumination.

parasites are detected ([Fig. 14\(a\)](#)). Random noises caused K-Mean clustering to be erratic and not able to properly segment the image. Only white blood cells were detected while a few of parasites were marked ([Fig. 14\(b\)](#)). Uneven illumination poses more problem to K-Mean clustering where the darker illumination was detected as one big cluster ([Fig. 14\(c\)](#)). K-Mean clustering was able to properly segment the area with lighter illumination in [Fig. 14\(c\)](#).

Recognition-Based Method

The scale-invariant feature transform (SIFT) in Fiji (JavaSIFT) was used to identify objects in the test images. SIFT attempted to extract and store key features of objects of interest from the input image; it then use these features to recognize the objects, e.g., tracking them. To demonstrate image tracking feature, a 15 degree rotated image of [Fig. 9](#) was used as a source image

Fig. 12 Result images using Watershed region-based method (a) In-focus image. (b) Image with noise. (c) Image with uneven illumination.

(see Fig. 15(a)); then SIFT extracted object features for future looking up. Using Fig. 9(a–c) as the input SIFT tracked those objects from Fig. 15(a) and produced the tracked results in Fig. 15(b–d), respectively. Yellow marks on these resulting figures reveal the tracked objects. SIFT is able to track (recognize) the objects using the stored key features on all variant of blood smear images.

Computational Intelligence Method

The trainable Weka segmentation with Bayesian classifier in Fiji is used in to analyze the previous malaria images. Prior to performing image segmentation, we assigned two groups of the training set, namely white blood cell and malaria parasite groups. After training, Bayesian classifier was able to properly segment the original blood smear image, where majority of white blood cells and parasites were correctly segmented (Fig. 16(a)). When encountering with random noise signals, however,

Fig. 13 Result images using Level set contour-based method (a) In-focus image. (b) Image with noise. (c) Image with uneven illumination.

the number of detected malaria parasites slightly dropped ([Fig. 16\(b\)](#)). The Bayesian classifier was able to largely detect the objects from both groups, except the region toward the rightmost end of the uneven illumination image that has the darkest shade ([Fig. 16\(c\)](#)).

Segmentation Techniques: Performance Criteria

Performance of an image processing algorithm can either be subjective (judging by feeling) evaluation or objective (judging by some measurable quality values) evaluation. Subjective evaluation is commonly conducted via human visual inspection; thus, it may be different from one evaluator to the other. In image segmentation, the performance of a segmentation method can be done

Fig. 14 Result images using K-Mean clustering-based method (a) In-focus image. (b) Image with noise. (c) Image with uneven illumination.

by visually comparing the original image to the segmented image. For objective evaluation, various mathematical measurement criteria are adopted for examples, misclassification error, edge mismatch, relative foreground area error, modified Hausdorff distance and region nonuniformity (Sezgin and Sankur, 2004). Misclassification error estimates the percentage of the misclassification between object and background. Edge mismatch calculates differences of the edge map between the original image and the corresponding segmented image. Relative foreground area error compares object properties in segmented image with the original one. The modified Hausdorff distance assesses the similarity of shape of segmented regions and compares with the ground-truth shapes. For the region nonuniformity measurement and comparison, the uniformity of objects and background from a segmented image are used to calculate variance of both segmented region. Since only objective evaluation may not be enough to effectively and correctly appraise a segmentation algorithm, subjective evaluation is also a common practice. Both objective and subjective evaluation.

Conclusion

The ultimate goal of image segmentation is to efficiently and effectively partition an image into meaningful objects or regions. Segmentation techniques have been widely studied and some of them have been implemented as tools at different levels, namely, lower level, middle level and high level. In this article, the segmentation techniques are categorized into seven classes, thresholding, edge-based, region-based, contour-based, clustering, recognition-based and computation-intelligence segmentations. Each class is evaluated based on three aspects, input constraints, output of methods and performance ([Table 1](#)).

Based on [Table 1](#), Thresholding methods, Edge-based methods, Region-based methods, Contour-based methods and clustering methods are not required prior knowledge; however, these methods are very sensitive and may fail when dealing with noisy image and uneven illumination image while the recognition methods and computational intelligence methods could perform better in both images but require a prior knowledge from user. The last two require high complexity and more stability comparing to the others. The contour-

Table 1 The evaluation of segmentation methods

Methods	Input constraints			Output of methods				Performance	
	Noise	Uneven illumination	Requiring prior knowledge	Edge	Region	Contour	Object of interest	High complexity	Stability
Thresholding	✗	✗	✗	✗	✓	✗	✗	✗	✗
Edge-based	✗	✗	✗	✓	✗	✗	✗	✗	✗
Region-based	✗	✗	✗	✗	✓	✗	✗	✗	✗
Contour-based	✗	✗	✗	✗	✓	✓	✗	✗	✓
Clustering	✗	✗	✗	✗	✓	✗	✗	✗	✓
Recognition	✓	✓	✓	✗	✓	✗	✓	✓	✓
Computational Intelligence	✓	✓	✓	✗	✓	✗	✓	✓	✓

Notes: ✗ means a method does not have an ability and ✓ means a method do have an ability.

Noises: unwanted interruptions which causes a number of pixels in the image to change in color and/or brightness.

Prior knowledge: addition data added to the system to help it identify, recognize, classify, differentiate or etc.

Uneven illumination: the level of brightness is not the same throughout the image.

Edge: where there is a sudden change of intensity between pixels. (most edges do not connect).

Region: an area of pixels which have similar properties.

Contour: boundary of regions which could be formed by a set of connected edges.

Object of interest: a meaningful object or region.

High complexity: computational complexity.

Stability: ability of a technique to remain unchanged under unexpected condition.

based method is stable as it can perform well on the uneven illumination image. Although there are many segmentation techniques have been proposed, they are not able to efficiently handle all possible image conditions as shown in the case study. Many factors such as image preparation process, acquisition process and complexity of an image itself present greater challenges for researchers to explore.

Acknowledgement

We would like to thank Napat Kaewkamnerd for preparing and processing those malaria images using various algorithms in Fiji presented in the case study section.

Biographical Sketch

Saowaluck Kaewkamnerd is currently a principal researcher and the head of Biomedical Signal Processing Laboratory at National Electronics and Computer Technology Center (NECTEC), National Science and Technology Development Agency (NSTDA), Thailand. Dr. Kaewkamnerd received her Ph.D. in Electrical Engineering from the University of Texas at Arlington, United States, in 2001. She has experienced in conducting research in biomedical image processing as well as other signal processing related projects.

Apichart Intarapanich is currently a researcher in Biomedical Signal Processing Laboratory at National Electronics and Computer Technology Center (NECTEC), National Science and Technology Development Agency (NSTDA), Thailand. He obtained his doctoral degree in Electrical Engineering from the University of Calgary, Canada in 2005. His specialized skills include Signal Processing for Telecommunication Section, implementing a real-time microphone array system for sound quality improvement, antenna design for WLAN, smart Antenna System development and PHS handset development.

Sissades Tongsimma received his Ph.D. in Computer Science and Engineering from the University of Notre Dame, United States in 1999. He worked at the National Electronics and Computer Technology Center (NECTEC), National Science and Technology Development Agency (NSTDA) until 2003. Since then he has moved to the National Center for Genetic Engineering and Biotechnology (BIOTEC), NSTDA as a senior researcher. Currently, he is now a principal researcher and head of Bioinformatics Laboratory, Genome Technology Research Unit at BIOTEC. His research interests include – omics Big data analysis as well as utilizing digital signal processing in his research. He serves as an executive committee of Asia Pacific Bioinformatic Network (APBioNET) and an associate editor of the journal of Human Genetics.

Introduction

The completion of the human genome project and a huge amount of data generated from the health care system have presented us with tremendous opportunities to understand and analyze our biological system in a greater detail. The data generated during clinical practice/research is used in finding its correlation with genomic data to obtain biologically significant insights. Due to the enormous size of data, the knowledge of information technology is required to store, integrate and analyze it. Analysis of complex biological data using knowledge of computer science, statistics and mathematics has resulted in the birth of a new field of life sciences, 'bioinformatics'.

Translational bioinformatics is an essential player in bench-to-bedside research, i.e., transformation of data into diagnostics, prognostics and therapeutics (Kann, 2010; Yan, 2011). It is the development of storage-related, analytic and interpretive methods by applying informatics methodology on voluminous biomedical and genomic data. It is particularly useful to find specific knowledge and medical devices that can be utilized by various stakeholders like biomedical scientists, clinicians and patients for improving patient care system, real time health monitoring and rational drug discovery. To understand translational bioinformatics, it is imperative to know the various types of data as well as the numerous tools and techniques to integrate and interpret these data (Altman, 2012). In this article, we describe various components of translational bioinformatics (Fig. 1).

Types of Datasets

The data utilized in translational bioinformatics can be broadly classified into biological and clinical data. An effective integration of these large heterogeneous datasets from classified areas, for instance molecular biology and clinical practice, provides clinically significant information (Sorani *et al.*, 2010).

Biological Data

The biological data encompasses molecular biology databases, which includes systematic arrangement of genomics, proteomics, metabolomics, microarray gene expression and phylogenetic data (Baxevanis, 2001). It can be further categorized into sequence, structure, functional or gene ontology database. Sequence databases include nucleic acid and protein sequences. Structure database encompasses RNA and protein structure. Functional database includes the function of gene and gene products. Functional or gene ontology is classified further based on molecular function, cellular component and biological process. If the functional database relates to physiological role of gene products, it is termed as molecular function database; if it determines the subcellular structures, it is called cellular component database; and if it determines the biological pathway in combination of other gene products, it is known as biological process database (Ashburner *et al.*, 2000). Gene ontology in conjunction with anatomical data

Fig. 1 Components of translational bioinformatics.

connects the parent and children phenotype. Similarly, biological process and disease progression, which are genetically determined, can be studied, and prophylactic action can be taken to slow down or avoid disease conditions from occurring.

The prominent biological databases implicated in the field of translational bioinformatics encompass data across metabolic/signaling pathways, protein-protein interactions, gene expression, polymorphisms, enzyme databases as well as drug related databases, which include drug structure, indication, pharmacological information, target structure/binding information and drug toxicity/adverse drug reactions (ADRs) data. Several databases and tools have been developed on metabolic/signaling pathways analysis, amongst them human metabolome database (HMDB), Kyoto Encyclopedia of Genes and Genomes (KEGG), Pathguide, pathDIP and XTalkDB are the most prominent and with distinct focus (Table 1).

HMDB provides information of human metabolite/metabolism, its detailed description, synonyms, structure, physico-chemical properties and reference NMR/MS spectra along with disease associations, pathway information, enzyme data, gene sequence data, SNP (single-nucleotide polymorphism) and mutation data (Wishart *et al.*, 2018). On the other hand, KEGG is a database and tool for analysis of gene function for genomes of 24 species including human, by linking the genomic information with cellular processes [such as metabolism, membrane transport, signal transduction and cell cycle] (Kanehisa and Goto, 2000). It has three databases, GENES database for genomic information, PATHWAY database for graphical representations of cellular processes and LIGAND database for the information about chemical compounds, enzyme molecules and enzymatic reactions. In contrast, Pathguide is a meta-database on

metabolic pathways, signaling pathways, transcription factor targets, gene regulatory networks, genetic interactions, protein-compound interactions and protein-protein interactions (Bader *et al.*, 2006). It is an overview of more than 190 web-accessible biological pathway and network databases, maintained by diverse groups in different locations. Recently, a resource pathDIP was developed that integrates core pathways (signaling/metabolic pathway databases) to predict biologically relevant protein-pathway associations (Rahmati *et al.*, 2017). It annotates 17070 protein-coding genes with 4678 pathways. Concurrently, a distinct tool XTalkDB was established for the analysis of signaling pathways and their crosstalk (Sam *et al.*, 2017). In addition, it covers the molecular components (e.g., proteins, hormones, microRNAs) that mediate crosstalk between a pair of pathways and the species and tissue.

Out of several protein-protein interactions databases, the most used are PANTHER (Protein ANALysis THrough Evolutionary Relationships), MINT (Molecular INTeraction Database) and DynamProt (Dynamics Proteomics) (Table 1). One of the first one to be developed was PANTHER that provides the function of uncharacterized genes (from any organism) based on their evolutionary relationships to genes with known functions (Mi *et al.*, 2005). It contains statistical models (Hidden Markov Models, or HMMs) to find out proteins (and their genes) family and subfamily that allows more precise evolutionary information. Subsequently, MINT database was established that catalogs physical interactions (obtained from large scale, genome wide experiment) between proteins stored in structured format (Chatr-aryamontri *et al.*, 2007). It also includes an integrated feature, HomoMINT for interactions between human proteins with orthologous proteins in model organisms. Another useful resource is DynamProt which is compendium of endogenously tagged human proteins expressed from its endogenous chromosomal location under its natural regulation (Frenkel-Morgenstern *et al.*, 2010). It illustrates the protein dynamics and localizations in individual living human cells following drug administration which is crucial for understanding effect of drug on cell.

Gene expression databases include CAGE, GeneWeaver, Gene Expression Barcode and WeGET (Table 1). CAGE (Cap analysis gene expression) is a highly sensitive and precise means of gene expression technique to produce high-throughput CAGE library (Kodzius *et al.*, 2006). It is primarily used to locate exact transcription start sites in the genome and allows investigation of promoter structure necessary for gene expression. It contributes to genome annotation, gene discovery and expression profiling. In comparison, GeneWeaver is a platform for integration of cross-species data and gene entity as well as scalable hierarchical analysis of investigator's experimental data with a community-built and curated data archive of gene sets and gene networks (Baker *et al.*, 2012). It provides means for data driven comparison of biological, behavioral and disease concepts. Gene Expression Barcode is the first database to provide absolute measures of expression for most annotated genes (McCall *et al.*, 2014). The expression of genes across tissues and cell types will help in generating hypothesis for gene function and clinical predictions using gene expression signatures. Recently, WeGET (Weighted Gene Expression Tool and database) was developed to predict new genes of a molecular system by correlating gene expression (Szkarczyk *et al.*, 2016). It ranks new candidate genes based on their weighted co-expression with that system and predict novel genes that co-express with a custom query set. On the other hand, BRENDA is one of the most comprehensive enzyme repositories (Schomburg *et al.*, 2004). It provides functional and molecular information of enzymes which is crucial for research of enzyme mechanisms, metabolic pathways and, furthermore, for medicinal diagnostics and pharmaceutical research. Additionally, PolyDoms is a whole genome database for polymorphism analysis and identification of non-synonymous coding SNPs (nsSNPs) with the potential to impact disease (Jegga *et al.*, 2007). It also predicts structural and functional impacts of all nsSNPs and identifies potentially harmful nsSNPs among multiple genes associated with specific diseases, anatomies, mammalian phenotypes, gene ontologies, pathways or protein domains.

The drug related databases cover drug structure database such as ZINC, DrugBank and SuperDRUG2, adverse drug reaction or toxicological databases such as CTD (Comparative Toxicogenomics Database), T3DB (Toxin and Toxin Target Database) and SIDER (Side Effect Resource) as well as drug target databases like TTD (Therapeutic Target Database) and HIT (Herb Ingredients' Targets). ZINC contains over 35 million molecules and provides their 3D structures for virtual screening against the specified target (Irwin and Shoichet, 2005) while DrugBank contains prescribing and pharmacological information including kinetics, dynamics, mechanism, target, interactions and metabolism pathway along with chemical, spectroscopic, patent information and 3D structure of a drug (Wishart *et al.*, 2008). In a similar vein, SuperDRUG2 provides indications, drug targets, side-effects, physicochemical properties, drug-drug interactions, pharmacological, chemical and regulator marketed drug/marketed drugs (Siramshetty *et al.*, 2018). In contrast, CTD provides the information about the effects of environmental chemicals on human health (Davis *et al.*, 2009). It also curates chemical – Gene interactions, chemical – Disease relationships and gene – Disease relationships to construct chemical – Gene – Disease networks by data integration. Similarly, T3DB is a database of toxic exposome (environmental exposures of human to an acutely toxic compounds) (Wishart *et al.*, 2015). It contains detailed information of toxic substances that is, chemical properties, descriptions, targets, toxic effects, toxicity thresholds, sequences (for both targets and toxins) and mechanisms. Recently, SIDER database was developed that hosts drug's side effects or adverse drug reactions [ADRs] (Kuhn *et al.*, 2016). TTD is a repository of known therapeutic protein and nucleic acid targets (Chen *et al.*, 2002). It covers sequence, 3D structure, function, nomenclature, drug/ligand binding properties and drug effects. Another distinct useful resource is HIT which is a database of herbal ingredients with protein target information (Ye *et al.*, 2011).

Some important binding site information databases are BindingDB and LigASite. BindingDB is a resource of binding affinity of protein-ligand complexes (Liu *et al.*, 2007). In comparison, LigASite is a repository of biologically relevant binding site in proteins for which at least one apo- and one holo-structure (ligand unbound and bound structure, respectively) are available (Dessailly *et al.*, 2008).

It is noteworthy to mention that the popular/useful general tools and databases of DDBJ, NCBI, EMBL, ExPASy as well as CLUSTALW and PDB have not been covered as they are beyond the focus/scope of this article.

Clinical Data

The data collected by physicians while treating patients and during clinical trials are termed as clinical databases (Blum, 1982). It includes comprehensive data pertaining to drug effects, electronic health records (EHRs), drug-drug interactions data, patients' medical histories and demographic data, pathology, diagnostic data and data of concomitant medications. The various databases where such clinical data are stored are MIMIC, ClinicalTrials.gov, EMA Clinical Data and Clinical Data Repository.

MIMIC (Multiparameter Intelligent Monitoring in Intensive Care) is a database of physiologic signals and vital signs captured from patient monitors (Saeed *et al.*, 2011). Clinical Trials (see "Relevant Websites section") is a resource of clinical trials and their outcomes, provided by the U.S. National Library of Medicine. EMA Clinical Data (see "Relevant Websites section") web portal hosts clinical data published under the European Medicines Agency. Clinical Data Repository (CDR) is a real time database that houses data from a variety of clinical sources such as 'UVA clinical data repository' (see "Relevant Websites section"), containing clinical information on over 1 million patients and 5 million clinical encounters, the clinical data repository ALLOY from Liaison (see "Relevant Websites section") and Inovalon's clinical data repository (see "Relevant Websites section").

Integration and Analysis of Data for Diagnosis and Treatment

After the collection of voluminous data on numerous diseases, the next crucial step is to store it systematically so that it can be easily retrieved/processed and analyzed. Volume, Variety and Velocity (3V's) are formidable challenges in such big data management (Sagiroglu and Sinanc, 2013). To manage these challenges, numerous tools and techniques have been developed. Big data could be structured (stored as arrays, files, records, tables or trees), unstructured (either in text-format for instance PowerPoint presentations, word documents, PDFs or non-text format like images, audios, videos) or semi structured [mixed] (Raghupathi and Raghupathi, 2014). Many approaches and technologies for storage and processing have been developed for better management and quick retrieval/response. Notable among these are Distributed File System (a server based application that allows remote data access of structured data to several clients simultaneously e.g., Apache Hadoop), NoSQL (for storage and retrieval of non-tabular data), Cloud Computing (for storage on a network of remote servers hosted on internet rather than a personal computer or local server) and Massive Parallel Processing (MPP, coordinated processing of a program by different processors working on different parts of the program) (Katal *et al.*, 2013).

Apart from storage and processing techniques, powerful and highly analytical tools are required to visualize, analyze and integrate the vast data. Some of the most popular tools toward this context include EHDViz (for data visualization), Theano (for deep learning), PreGel, Apache Giraph and Gephi (for graph processing) as well as Apache Mahout, Spark MLlib and Weka (for machine learning) (Shameer *et al.*, 2017). Machine and deep learning techniques are used to process and analyze variety of data with high velocity. Machine learning is a part of artificial intelligence (AI) that trains the computer to perform the desired task automatically and more efficiently and accurately. There are different machine learning techniques like supervised learning (viz. Naïve Bayes Classifiers, Decision Tree, Support Vector Machine), unsupervised learning, reinforcement learning, deep learning, association rule learning and numeric prediction (Tan and Gilbert, 2003). Towards this end, several web servers and programs have been developed. For instance, an algorithm like Decision Support Systems (DSS), a program which facilitates complex decision making and problem solving by compiling, either graphically or as written report, massive reams of data to provide analytical result (Somek and Hercigonja-Szekeres, 2017). KDSS (Knowledge-based Decision Support System) is an example of DSS using a knowledge based coding to provide a novel workflow for protein complex extraction (Fiannaca *et al.*, 2013).

Cardiovascular diseases, central nervous system (CNS) diseases, respiratory diseases, cancer, diabetes, tuberculosis and viral diseases (like HIV, hepatitis, dengue, influenza/flu, measles) are the major cause of deaths globally (WHO report 2017). Amongst these, computational tools and databases implicated in cancer (Blekherman *et al.*, 2011), tuberculosis (Sharma *et al.*, 2015) and viral diseases (Sharma and Surolia, 2011) have already been compiled/described in great details. Prominent tools for cardiovascular, CNS and respiratory diseases as well as diabetes research are listed in Table 2. It also enlists useful tools that are not specific to any particular set of diseases.

CADgene, T-HOD or CardioSignal are gene databases associated with cardiovascular diseases (Table 2). CADgene is a comprehensive resource and integration tool for coronary artery disease genes (Liu *et al.*, 2011). It provides detailed information about the size of case-control, population, SNP, odds ratio and P-value, for each gene. T-HOD is a gene database for hypertension, obesity and diabetes (Dai *et al.*, 2013). It has a gene/disease identification system and a disease-gene relation extraction system to affirm the association of genes with these three diseases. CardioSignal is a repository of transcriptional regulation involved in heart development and cardiac hypertrophy (Zhen *et al.*, 2007). On the other hand, PubAngioGen is a comprehensive database for exploring the connection between angiogenesis and diseases at multi-levels including protein-protein interaction, drug-target, disease-gene and signaling pathways (Li *et al.*, 2015). In contrast, miRHrt is a database of microRNA function in heart development and by computational analysis it illustrates the correlation of differentially expressed miRNAs with cellular functions and heart development (Liu *et al.*, 2010). CARFMAP is an interactive cardiac fibroblast pathway map derived from biomedical literature (Nim *et al.*, 2015). It enables identification of new genes that are relevant to cardiac research and differentially regulated in high-throughput assays. Another useful tool is ECGSYN (see "Relevant Websites section") that generates a synthesized ECG signal with user-settable mean heart rate, number of beats, sampling frequency, waveform morphology (P, Q, R, S, and T timing, amplitude and duration), standard deviation of the RR interval, and LF/HF ratio (a measure of the relative contributions of the low

Table 2 Disease-specific tools and databases

Disease	Website	Key feature(s)	CI ^a	Access ^b	URL
Cardiovascular diseases	CADgene	Coronary artery disease (CAD) gene database	9.5	W	http://www.bioguo.org/CADgene/about_us.php
	CardioSignal	Repository of transcriptional regulation in cardiac development and hypertrophy	0.8	W	http://www.cardiosignal.org/index.html

and high frequency components of the RR time series to total heart rate variability). Additionally, a method for simulating atrial fibrillation has been developed using ECGSYN (Healey *et al.*, 2004). The simulator uses a timing operator to switch from generating normal ECG morphologies to atrial fibrillation.

Several genomic databases for central nervous system diseases include AlzGene, PDGene, ADHDgene, EpilepsyGene, AutDB or SZGR (Table 2). AlzGene is a resource of Alzheimer disease susceptibility genes with statistically significant allelic summary

(Bertram *et al.*, 2007). It also performs systematic meta-analyses for each polymorphism with available genotype data. Similarly, PDGene is a meta-analyses database of genes associated with Parkinson's disease (Lill *et al.*, 2012). ADHDGene is a genetic resource and analysis platform for Attention Deficit Hyperactivity Disorder [ADHD] (Zhang *et al.*, 2012). EpilepsyGene is a repository of genes and mutations related to epilepsy (Ran *et al.*, 2015). It also includes functional annotation, gene prioritization, functional analysis of prioritized genes, and overlap analysis focusing on the comorbidity. In contrast, AutDB is a well classified (as per genetic variation of candidates identified from genetic association studies, rare single gene mutations and genes linked to syndromic autism) database of genes connected to Autism Spectrum Disorders [ASD] (Basu *et al.*, 2009). It covers gene annotation for their relevance to autism, along with an in-depth view of their molecular functions. Schizophrenia Gene Resource (SZGR) catalogs genetic data from association studies, linkage scans, gene expression, literature, gene ontology (GO) annotations, gene networks, cellular and regulatory networks across all mycobacterial spe, as well as microRNAs and their target sites (Jia *et al.*, 2010). Another useful tool is Genes to Cognition database (G2Cdb) that houses sets of genes and biochemically isolated (from mammalian synapse) or experimentally elucidated proteins (Croning *et al.*, 2009). It links genes, proteins, (patho)physiology, anatomy and behavior across species. Recently, a manually curated database Nervous System Disease NcRNAome Atlas (NSDNA) was established that provides comprehensive experimentally supported associations about nervous system diseases (NSDs) and noncoding RNAs (ncRNAs) (Wang *et al.*, 2017).

The databases/tools dedicated for diabetic research and study are T1DBase, T2D-Db, Type 2 Diabetes Knowledge Portal and Islet Regulome Browser (Table 2). T1DBase is a web server of molecular genetics to study susceptibility and pathogenesis of type-1 diabetes (T1D) (Smink *et al.*, 2005). It covers annotated genome sequence for human, rat and mouse; information on genetically identified T1D susceptibility regions in human, rat and mouse, and genetic linkage and association studies pertaining to T1D; the Beta Cell Gene Expression Bank, which reports expression levels of genes in beta cells under various conditions, and annotations of gene function in beta cells; data on gene expression in a variety of tissues and organs; and biological networks across all mycobacterial spe from KEGG and BioCarta. It also contains tools like GBrowse (genome browser), site-wide context dependent search, Connect-the-Dots (for connecting gene and other identifiers from multiple data sources), Cytoscape (for visualizing and analyzing biological networks), and the GESTALT workbench (for genome annotation). On the other hand, T2D-Db (Type 2 diabetes database) provides integrated data on molecular components involved in the pathogenesis of T2D of human, mouse and rat (Agrawal *et al.*, 2008). It also contains information on candidate genes, SNPs (Single Nucleotide Polymorphism) in candidate genes or candidate regions, Genome-Wide Association Studies (GWAS), tissue specific gene expression patterns, EST (Expressed Sequence Tag) data, expression information from microarray data, pathways, protein-protein interactions and disease associated risk factors. Similarly, 'Type 2 Diabetes Knowledge Portal' is a repository of DNA sequence, functional and epigenomic information, and clinical data on T2D and its macro- and microvascular complications, and creating analytic tools to analyze these data (see "Relevant Websites section"). Islet Regulome Browser is a tool for exploring pancreatic islet epigenomic and transcriptomic data and provides interactive access to GWAS variants, different classes of regulatory elements, together with enhancer clusters, stretch-enhancers and transcription factor binding sites in pancreatic progenitors and adult human pancreatic islets (Mularoni *et al.*, 2017).

The databases involved in research of respiratory diseases are IGDB.NSCLC, LGEA, MyMpn and SEGEL (Table 2). IGDB.NSCLC is an integrated genomic resource for non-small cell lung cancer (Kao *et al.*, 2012). It covers aberrant expressed genes and microRNAs, somatic mutations and experimental evidence and clinical information of non-small cell lung cancer patients. In contrast, LGEA (Lung Gene Expression Analysis) is a gene expression database for lung diseases (Du *et al.*, 2017). It provides different tools such as LungGENS (for single cell transcriptomes analysis), LungSortedCells (for sorting lung cell population), LungDTC (for development time course analysis) and LungDisease (for disease analysis). MyMpn is an online resource for studying the human pathogen *Mycoplasma pneumonia* and hosts data obtained from gene expression profiling experiments, gene essentiality studies, protein abundance profiling, protein complex analysis, metabolic reactions and network modeling, cell growth experiments, comparative genomics and 3D tomography (Wodke *et al.*, 2015). Concurrently, a distinct tool SEGEL (Smoking Effects on Gene Expression of Lung) for visualizing smoking effects on human lung gene expression was developed (Xu *et al.*, 2015). It integrates expression microarray data sets from trachea epithelial cells, large airway epithelial cells, small airway epithelial cells and alveolar macrophages.

In addition to disease-specific tools, there are several general tools to integrate and analyze association between gene and disease progression such as DisGeNet, DistiLD, Imprinted Gene Catalogue, LncRNADisease, and 'Organ System Heterogeneity DB' (Table 2). DisGeNet integrates expert-curated databases with text-mined data, covers information on Mendelian and complex diseases and includes data from animal disease models (Pinero *et al.*, 2015). It features a score based on the supporting evidence to prioritize gene-disease associations. In comparison, DistiLD focuses on disease-associated SNPs and genes in their chromosomal context (Palleja *et al.*, 2012). Another useful tool is Imprinted Gene Catalogue that helps in examining parental origin trends for different types of spontaneous mutations (Glaser *et al.*, 2006). LncRNADisease is a database for long-non-coding RNA-associated disease diagnosis, treatment and prognosis (Chen *et al.*, 2013). In addition, 'Organ System Heterogeneity DB' displays distribution of phenotypic effects across organ systems along with the heterogeneity value (Mannil *et al.*, 2015).

Strategies and Scope of Translational Bioinformatics

Translational bioinformatics assists in bringing laboratory work to clinical world as well as helps in drug discovery, clinical research, surveillance of approved drugs and patient-specific therapy regimes.

Drug Discovery

Drug molecule development

The important aspects of drug molecule development include:

Molecular variation

The efficacy and safety of any new compound is first evaluated in an animal model under preclinical studies. We find that several of these new compounds show efficacy in animal models, but they fail in humans and vice-versa. The reason of this efficacy variation is molecular variation between humans and animals (Shanks *et al.*, 2009; Buchan *et al.*, 2011). The two models might have distinct molecular pathologies. Translational bioinformatics helps to analyze the molecular variation in data obtained from the animal models and humans, and helps to take decision whether further development should proceed or not (Cox *et al.*, 2011). The drugs which are efficacious during preclinical phase and get rejected in late clinical phase, increase the cost of drug development. Furthermore, the safety of drugs could be an issue, as molecule may be safe in animal but can be life threatening in case of human beings (Ioannidis, 2012). The cost of drug development has been increasing steadily due to drug failure, the major cause of which is lack of clinical efficacy as well as toxicity. As per the executive summary prepared by FDA in October 2017, the estimated cost of failed clinical trials ranges from \$800 million to \$1.4 billion. Translational bioinformatics can help in pre-analysis and ensure cost effectiveness and safe drug development.

Similarly considering the reverse case, several molecules which might be life saving for human beings, are discarded due to their failure in animal models, and thus are not studied in humans. So, translational bioinformatics may help in identifying drugs, which may be efficacious in humans.

Target identification/rational drug discovery

The discovery of drugs based on the knowledge of the target is termed as rational drug discovery. There are several inventive approaches to find out and characterize the target. The techniques of transcriptional bioinformatics, metabolic and signaling pathway analysis, knowledge of interacting proteins and information on enzyme activity are used as a protocol for target identification/rational drug discovery. Numerous bioinformatics tools/web servers (Table 1) are frequently used to find target structure and binding site information that can translate data into drugs.

Clinical research

Clinical research comprises of pharmacogenomics for optimal treatment and biomarker efficacy.

Pharmacogenomics for optimal treatment

The study of how genes affect individual's response to the drug is termed as pharmacogenomics, which could be studied as a part of precision medicine (Thorn *et al.*, 2010). The available genomic and phenomic data studied in relation with Electronic Medical Records (EMRs) and pharmacology help to evaluate safe and effective medicine and transplant for individuals.

Characterization of patient's genome by high throughput sequence analysis and comparative analysis with standard database gives an idea whether any gene is responsible for disease expression (Sarkar *et al.*, 2011). The inhibitor of that gene will only be effective in the patient who is affected due to overexpression of it, not by any other cause. The knowledge of pharmacogenomics helps in the selection of people with desired genetic composition for optimal treatment, with minimum side effects.

Biomarker (tracking) efficacy

A biomarker is a biomolecule that provides early diagnosis of a disease or its state of progression (Xia *et al.*, 2013). It is utilized to quantify drug efficacy, and identify drug targets and mechanism. Biomarkers that monitor specific physiological or pharmacological phenomenon can be used to select multiple therapeutic targets of a drug molecule (Kusumegi *et al.*, 2004).

Post-approval surveillance

The safety of drugs and repurposing drugs for new ailments are important considerations once drugs get approved for marketing.

Drug safety monitoring

To monitor safety of drugs, adverse drug reactions (ADRs) data are prepared. ADRs data can be easily obtained by transforming the big data (refers to electronic health records, administrative or health claims data, disease and drug monitoring registries) for pharmacovigilance system (Harpaz *et al.*, 2016). Sometimes, this data helps in finding new indications for existing drugs. A beneficial side effect could be considered as an additional therapeutic effect of the drug. For example, minoxidil, which is a potassium channel potentiator, is used as an antihypertensive drug, with the side effect of hypertrichosis (excessive growth of hair). This is considered as an additional therapeutic benefit and is used to control alopecia (hair loss or baldness).

Some ADRs are also observed in persons with specific genetic make-up. ADR databases help to identify the correct set of patients for a particular drug molecule. In addition, the analysis of these ADR database gives an idea about extra effects of the drugs and the pharmacological mechanism of drug action (Harpaz *et al.*, 2016; Abernethy *et al.*, 2011).

Drug repurposing

The reuse of already approved drugs for new diseases is termed as drug repositioning or repurposing. Since drug development and approval are costly and time consuming, this is an efficient way to bypass the early development phase and proceed directly with clinical trials for possible new diseases.

Translational bioinformatics strategies for repurposing involve finding new targets for approved drug molecules, by protein-protein, and drug-protein interactions, pathway analysis and similarity in gene expression during the progression of different diseases that may involve same molecular mechanism. Furthermore, high throughput screening of a drug's chemical structure against the various receptors allows finding new targets.

Patient-Specific Treatment Regimes

These include personalized medicine and real-time health monitoring systems.

Personalized medicine and pharmacogenomics

An individual genetic/molecular variation predicts disease susceptibility and responses to therapeutic agents. Biological data of people of various demographic conditions enable us to understand differential treatment approach required by individuals of different types of genes, lifestyle and environments (Reynolds, 2012). The data related to medical history of the patient is a key requirement for personalized medication. Apart from diagnostic reports, metagenomic analysis (environmental analysis) and genetic testing of patients are utilized to compare and analyze the class of medication that must be prescribed to the patient. The term 'personalized medicine' is used for group of people having similar gene type, lifestyle and environments, providing a basis for similar treatment strategies.

Although the term 'precision medicine' is relatively new, the concept has been a part of healthcare for more than a century. For instance, specific blood group of people can be transfused with only specific types of blood due to their antigen, which is result of their genetic composition. Presently, precision medicine is being intensively studied and, if future, could lead into new era of medicine.

Real-time health monitoring

To get the real time data of the individual medical aspects, various real time health monitoring wearable or implantable devices are available, for e.g., Fitbit Surge (heart rate, activity, sleep, and caloric burn), iHealth BP5 (blood pressure), iHealth glucometer (Blood glucose), Muse Headband (EEG), Scanadu Scanflo (urine analysis), Zephyr BioPatch (respiratory rate, ECG), Empatica E3 (photoplethysmograph, electrodermal activity). The data provided by these devices are known as Electronic Health Records (EHRs) or Electronic Medical Records (EMRs), which are integrated to clinical repositories or biobank by machine learning technology and predictive analysis offered by various tools and programs such as (i) eMERGE (see "Relevant Websites section"), a tool to combine DNA biorepositories with EMR systems for large scale, high-throughput genetic research in support of implementing genomics (Gottesman *et al.*, 2013a); (ii) CLIPMERGE PGx, a program for personalized medicine through EHRs and genomics-pharmacogenomics (Gottesman *et al.*, 2013b); (iii) i2b2 (see "Relevant Websites section"), integrating biology and bedside, a translational engine of patient's clinical data (Takai-Igarashi *et al.*, 2011).

EMRs are standard medical and clinical data gathered and stored electronically by health care provider. Analysis of these data with respect to available database helps to understand and identify the transition of the healthy state of the person to the diseased state, and the individual's disease progression (Shameer *et al.*, 2017). Most prominent databases linked with EMRs are (i) BioMe BioBank (see "Relevant Websites section"), a database of blood samples and health information, (ii) HarmoniMD (see "Relevant Websites section"), a repository of electronic clinical documents and cloud based EHR system, and (iii) HealthVault (see "Relevant Websites section"), a platform to store personal health information and generate insight from it.

Drug Interactions

Drug-drug interaction (DDI) can occur when two or more drugs are co-administered to a patient. It can lead to changed systemic exposure, resulting in variations in drug response of the co-administered drugs. DDIs generally occur due to inhibition of the metabolism for one drug by the other. It leads to a rise in plasma concentration of the drug whose metabolism is inhibited. The therapeutic index of the drug that has increased concentration in plasma could be decreased, leading to adverse reaction or increase in toxicity. The drug efficacy databases and DDI databases, play crucial roles during concomitant medication and avoid risk of adverse impact on the patient (Duke *et al.*, 2012). Evaluation of potential drug interactions also provides the idea about physiological pathways of its kinetics and dynamics.

Computational Tools Implicated in Drug Discovery

Multitude of biological and clinical databases have led to the development of tools for drug discovery (Table 3). It includes data integration software, virtual screening or structure activity relationship tool, docking, modeling or interaction visualization tool, disease progression or signaling pathway analysis tools.

Table 3 Drug discovery tools and web servers

Website	Key feature(s)	CI ^a	Access ^b	URL
CAVER analyst	For calculation, analysis and real time visualization of static or dynamic protein tunnel interaction	20.2	W	http://www.caver.cz/index.php

ConsensusPathDB, PharmGKB and PROMISCUOUS are database integration and analysis tools that integrate -omic (genomic, proteomic or metabolomics) data with signaling or biochemical pathway data to identify drug targets. ConsensusPathDB integrates and provides visualization of diverse functional interactions (protein – Protein interactions, biochemical reactions, gene regulatory interactions) and more than 1700 metabolic/biochemical pathways of human and provides visualization of interaction networks and substructures derived from the integrated interaction network (Kamburov *et al.*, 2009). On the other hand, MycoRegDB delineates regulatory pathways/networks across all mycobacterial species (Sharma *et al.*, 2009; Sharma and Surolia, 2013, unpublished data). This in turn will pave way for identification of new drugs for tuberculosis. In contrast, PharmGKB provides pathway and pharmacogene summary by integrating genotype, molecular as well as clinical knowledge and helps in investigating how genetic variation affects drug response (Thorn *et al.*, 2013). PROMISCUOUS is a database for understanding and prediction of off-target effects of drugs and allows a rational approach for drug-repositioning (von Eichborn *et al.*, 2011). It measures structural similarity for drugs and connects it to protein-protein interactions to establish and analyze networks responsible for its known side-effects. Based on this network-based approach, it helps in drug-repositioning. Another useful tool is MLViS that classifies molecules as drug-like and nondrug-like based on various machine-learning methods, including discriminant, tree-based, kernel-based, ensemble and other algorithms (Korkmaz *et al.*, 2015). Subsequently, it helps in performing virtual screening of drug like molecules against the target to find out active drug compounds. NNScore is a tool for scoring function (score is used during virtual screening) based on neural network for the characterization of protein-ligand complex (Durrant and McCammon, 2010). A distinct tool SuperTarget has also been developed that integrates drug-related information like medical indication, adverse drug effects, drug metabolism, pathways and Gene Ontology to find out drug-target relations (Gunther *et al.*, 2008). ‘CAVER Analyst’ is a graphic tool for interactive real-time visualization and analysis of tunnels and channels in static and dynamic protein structures (Kozlikova *et al.*, 2014). Molsoft contains a quantitative structure activity relationship (QSAR) tool, which helps in drug designing by providing the quantitative information about functional group’s position/type present in drug molecule (see “Relevant Websites section”). In addition, Drug2Gene is a database that combines the compound/drug-gene/protein information and integrates it to identify compounds targeting a given gene product or for finding all known targets of a drug (Roider *et al.*, 2014).

Discussion

Translational bioinformatics has opened new doors for churning out precious information from the existing knowledge of human health, disease progression mechanism, prophylactic conditions and human variation. The current challenges in healthcare are cost, ADRs, efficacy variance, late diagnosis and high rate of organ failures. These challenges can be addressed in the patient if the right medication can be administered at an appropriate time. Against this backdrop, it becomes important to understand the genetic makeup of an individual as well as the impact of environmental and demographic factors to provide right medication in sync with the requirement. The biological database helps us in this endeavor, provided we have scientific base for finding gene interactors and gene(s) responsible for disease progression and its molecular mechanism. Various relevant tools help us to understand the connection between genotype and phenotype via proteomic and metabolomics information.

On the other hand, the structure-function relationship provides information for drug designing, pharmacophore modeling and QSAR studies, thereby leading to drug discovery. Numerous molecules are now available in market or under development owing to this rational method of drug discovery rather than the traditional methods of study. It has not only reduced the cost of pharmaceutical industry significantly but also provided motivation for new findings or synthesizing analogs of higher efficacy and least toxicity. In addition, translational bioinformatics has proved the significance and utility of biomarkers by studying systemic interactions among genes, metabolites, tissue system, drugs and intermediate molecules, including environmental factors. Bio-markers information helps in timely diagnosis, and thereby ensures better treatment outcomes.

Similarly, the clinical information about patient's conditions, disease progression, adverse drug reactions (ADRs), pathological, diagnostics and wellness reports provide records for real time health monitoring by comparing and analyzing with the help of relevant tools and applications. It provides information about disease progression that helps to take required treatment at an appropriate time. Furthermore, the integration of these data help in the prediction of the rate of occurrence of any disease based on pollution condition or type, socioeconomic and geographic distribution. This helps to suggest further precaution or prophylactic action to the group of individuals. The total environmental exposure of human is termed as 'exposome', which indicates the disease susceptibility (e.g., lung cancer, skin cancer, asthma, allergy, baldness and deficient to specific micronutrient) based on exposure to the ambient environmental conditions (e.g., air-quality, smoke, radiations and specific nutrient chelators in food). Some devices are also there to measure exposome along with EMRs.

Summary

In the new era of data-driven healthcare evolution, translational bioinformatics is a crucial approach for drug discovery and development process. The innovative translational and computational analysis approaches are making a great impact on discovery, preclinical, clinical and post launch of a drug. The computational study saves millions in cost of drug development as compared to classical method. It gives rational approach, which reduces the chance of failure as compared to blind testing. It facilitates a better drug designing of improved efficacy since structural data of receptors gives fair idea about pharmacophore modeling and quantitative structure activity relationship (QSAR) studies. Additionally, the sequence data helps in generating model of unknown structures with the help of several tools, which are used to study its interaction with drug molecules. It also enables to understand and decipher the mechanism of drug molecules by analyzing the functional data and laboratory verification. The development of various databases in health care system is a huge resource for advancement and evolution of safe and efficacious medicinal system. As discussed above, the clinical data independently or in integration with biological data help to find out new drug or improved safety prescriptions. In addition, proper selection of patients during trial improves design of the trial and its success rate. Personalized medicine and real time health monitoring is a new era in the medical history, wherein huge efforts are being made. It has a great role in preventing life threatening disease like cancer where proper drug selection is still a challenge. Translational bioinformatics is an emerging field with lot of opportunities in medical advancement with development of algorithms, tools, programs and methods in order to find out significant information from available databases. Hopefully in the near future, translational bioinformatics with utilization of artificial intelligence will revolutionize medical landscape.

Introduction

Translational bioinformatics (TBI) is an emerging field with great potential to assist clinicians to achieve success in the advancement of personalized medicine. Translational bioinformatics (TBI) is very young field at the horizon of TBI comprises molecular bioinformatics, clinical informatics, genetics, biostatistics, health informatics and. The convergence of these fields into one makes TBI a prime component of biomedical research. The American Medical Informatics Association defined TBI as “the development of storage, analytic, and interpretive methods to optimize the transformation of increasingly voluminous biomedical data, and genomic data, into proactive, predictive, preventive, and participatory health” (see “Relevant Website section”). TBI integrates biological findings with the clinical information by using advanced computing environments and methodologies to bridge the gap between bench and bedside. TBI mainly focus on development of novel techniques for the integration of biological and clinical data and applying bioinformatics to translate the biological observations to practical application in a clinical setting. After the completion of the human genome project, clinicians acknowledge the potential use of the data generated, that it might give valuable information to know more about the basic mechanism of a human body. This accelerated the use of genome sequencing techniques resulting in the generation of a massive data that helps characterize the transcriptome, the proteome, and the metabolome (Altman, 2012). TBI not only created new knowledge but also gave new insights into underlying genetic mechanism of a disease (Londin and Barash, 2015). The four main foci of bioinformatics are clinical genomics, genomic medicine, pharmacogenomics, and genetic epidemiology (Fig. 1). These form the foundation of practices used by TBI to bridge the gap of research discoveries to clinical applications and their respective databases (Sarkar *et al.*, 2011).

In order to provide precision medicine-based therapies, heterogeneous data from clinical evaluations, bio-specimens and experimental investigations to characterize an individual patient’s disease progression need to be integrated. This requires systematic collection, standardized storage, and analysis of data (Jonnagaddala *et al.*, 2016, 2014). This integrated information often resides in several public and private databases. These comprehensive databases have become increasingly important among the researchers for hypothesis generation, validation, and verification in many areas such as drug discovery and clinical research (Zou *et al.*, 2015). The TBI rely on the four fundamental pillars of bioinformatics i.e., clinical genomics, genomic medicine, pharmacogenomics, and genetic epidemiology. These emerging fields laid down the foundation of approaches used in TBI to

Fig. 1 Schematic illustration of four main areas of bioinformatics that laid the foundation of the approaches used by TBI to bridge the gap between bench and bedside.

bridge the gap between bench and bedside. This article discusses various TBI databases. These databases have already made a significant impact worldwide and continue to assist clinicians and other health care providers to implement personalized medicine. We also briefly discuss about the use of TBI databases in clinical genomics and in drug discovery and repurposing.

Translational Bioinformatics Databases

Over the decade, several TBI databases are developed to store biological findings, high-throughput data; scientific studies, published literature, and computational analysis. Most of the data stored in these databases contain evolving information which can give new insights to the researchers and help to facilitate the advancement of existing research. Here in this article we present few databases which are frequently used by diverse groups including from biologists to bioinformaticians.

Clinical Genomics Databases

Genomics is a study of the function, evolution, structure, and inheritance of the entire set of genetic material of an organism. Genomics involves the study of genes at all levels (e.g., DNA, mRNA, protein, cell, and tissue). The genomic studies become very efficient after the development of advanced technologies to facilitate high throughput sequencing and functional analysis. These technologies generate huge amounts of data that consist of DNA and protein sequence, data generated from various functional analysis and genetic mapping data. Most data are freely available for the public to access. Some of the popular genomic databases are: Clinical Genomic Database (CGD) (Solomon *et al.*, 2013) is a valuable resource of known genetic conditions contains the data of single gene alteration. COXPRESdb (Obayashi *et al.*, 2012) provides co-expression relationship for several animal species. COXPRESdb is a resource to discover a function of new gene candidates or to identify functional modules in metabolic and signaling pathways. Another popular database is “Database of genetic variants” (DGV) (MacDonald *et al.*, 2014) provides comprehensive information of structural variant in the human genome (healthy controls). dbVar is a publicly accessible, and freely available database that is developed and maintained by the National Center for Biotechnology Information (NCBI). The dbVar database is slightly different from DGV, as it also contains structural variation information for human but also includes clinically relevant structural variation data from ClinVar. The human genome database (GDB) is a public repository mainly focus on human genes, clones, polymorphism, and STSs (Letovsky *et al.*, 1998).

Genomic Medicine Databases

Genomic medicine is an emerging medical field which necessitates the use of an individual’s genomic information to advance preventive treatment strategies and tailor-made treatments. Genomic medicine is adequate to make a mark on the personal healthcare by understanding the underlying mechanism of a disease. Here we will briefly describe several web resources that fall under the genomic medicine category. Cancer genome interpreter (CGI) is a web interface mainly developed to identify validated oncogenic alterations and to anticipate cancer driver genes among mutations of unknown significance. This CGI also have a comprehensive catalogue of validated oncogenic alterations, biomarker of drug response, cancer genes, and cancer types (Tamborero *et al.*, 2018). ClinVar is a freely available archive which addresses the relationship of human variability and ascertained health condition with detailed interpretation knowledge (Landrum *et al.*, 2016). The database of curated mutation (DoCM) in cancer is an open resource with the collection of biological important cancer variants (Ainscough *et al.*, 2016). OncoKB, a precision-based oncology knowledge base provides evidenced based information of individual somatic mutation and structural alterations (Chakravarty *et al.*, 2017). Like OncoKB, Precision Medicine Knowledge Base (PMKB) is also precision-based knowledge base valuable resource for cancer variants and represented the interpretations in structured manner. This knowledge base is freely accessible which allows the user to submit interpretations as well as modify existing information (Huang *et al.*, 2017). Personalized cancer therapy (PCT) is a knowledge base for precision oncology that was developed to suggest a potential therapy to patients and clinicians based on particular tumor biomarkers.

Pharmacogenomics Databases

The pharmacogenomics is a combination of pharmacology and genomics where genomic information is used to examine the individual response to a drug agent. Pharmacogenomic research and discovery strongly assist health practitioners and clinicians in determining the correct drugs and accurate dosage for each individual, which may prevent adverse drug reaction and helps in the advancement of drug therapy (Zhang *et al.*, 2015). In this section, we will describe most commonly used pharmacogenomic database. The PharmacODB (Smirnov *et al.*, 2018) is the largest collection of cancer pharmacogenomic studies. This database allows researchers to explore the information of a particular drug or cell line across publicly available datasets and compare the dose-response data for a specific cell line – drug pair from any of the studies included in the database. The pharmacogenomic knowledgebase (PharmGKB) is a curated collection of genetic variants, drug labels, genes, drugs and their associations and relationships (Whirl-Carrillo *et al.*, 2012). The Clinical Pharmacogenetics Implementation Consortium (CPIC) is an international consortium formed in 2009 with the aim to address the implementation of genetic test results into an actionable form to make decision for affected drugs. This web resource is the collection of updated, detailed gene/drug clinical practice guidelines. The

DrugBank is a freely available resource containing drug and drug target related information. This database is full of both bioinformatics and chemo-informatics resources. The SCAN database is the collection of genetic and genomic data with multiple algorithms that can be used in data mining. This database consists two categories of SNPs: (1) Physical-based annotation and (2) functional annotation. CTDBase curates scientific data that describes relationships among chemicals/drugs, genes/proteins, diseases, taxa, phenotypes, GO annotations, pathways, and interaction modules. The primary goal of CTDBase is to enhance the understanding of the effects of environmental chemicals on human health on the genetic level, a field called toxicogenomic (Davis *et al.*, 2017). The drug gene interaction database (DGIdb) provides information of candidate genes or drugs against the known and potentially druggable genome (Cotto *et al.*, 2018).

Genetic Epidemiology Databases

Genetic factors or genes have all detailed information of our body; it has a crucial role in maintaining health and causing disease. Genetic epidemiology is the study of the role of genetic factors in our body for the determination of inherited disease among families. Such study can lead us to understand the underlying mechanism of genetic factors. In this topic we will discuss several genetic epidemiology databases include neuropsychiatric disorders, infectious diseases, breast cancer, kidney disease, cardiovascular disease, diabetes and aging. Neuropsychiatric disorder de novo mutation database (NPdenovo) is a huge collection of new (de novo) mutations causing mental disorders (autism spectrum disorder, intellectual disability, epileptic encephalopathy, schizophrenia and unaffected siblings). All information is identified by using whole-exome sequencing (Li *et al.*, 2016). BRCA share is a largest database containing clinical BRCA gene variants responsible for breast cancer (Beroud *et al.*, 2016). T2D@ZJU is comprehensive knowledge base contained information of type 2 database. All information are categorized in three types retrieved from pathways database, Protein-Protein Interaction (PPI) database and research articles (Yang *et al.*, 2013). Type 2 diabetes genetic association database (T2DGADB) is developed to provide valuable information to the clinicians about the genetic risk factors, which plays vital role in the development of Type 2 diabetes (Lim *et al.*, 2010). The clinical database for kidney disease (CDKD) includes physiological data of kidney patients (Singh *et al.*, 2012). CardioGenBase, a comprehensive database for major cardiovascular disease (MCVDs) and causing genes. Allgene/protein information are collected from MCVD based literatures. This database provides valuable information to the clinicians to unveil novel disease mechanism (Alexandar *et al.*, 2015). Alzforum is an information resource aiming to help researchers to accelerate discovery and development of diagnostics and treatments for Alzheimer's disease and related disorders. This

information resource has several databases dedicated to Alzheimer's disease. A list of few currently available TBI databases are presented in [Table 1](#).

Recent Advances

Drug discovery is a process of designing potential medicines to stop or reverse the effects of the disease. This process starts after the diagnosis and characterization of symptoms affecting human life ([Xia, 2017](#)). Drug discovery needs a large investment, enormous time and effort. The average time frame to develop a drug is 10–17 years. Despite this, Food and Drug Administration (FDA) approved a very small number of drugs every year ([Jadamba and Shin, 2016](#)). Drug repurposing is an approach that addresses these issues to some extent. It takes advantage of the fact that approved drugs and many left alone compounds have already been tested in humans and detailed information of clinical and pharmacokinetic data is available ([Astin *et al.*, 2017](#)). The applications of TBI approaches are on a high demand in the pharmaceutical industry especially in drug discovery and drug repositioning aspects. By using the new knowledge created in the TBI databases, pharmaceuticals are addressing the identification and development of potential drugs ([Buchan *et al.*, 2011](#)). Several sophisticated computational tools are employed to analyze these databases that help in decision making in several aspects of drug discovery and development.

Conclusion

In summary, in this article we discussed the role of TBI databases and also presented mostly commonly used databases by diverse group of users, including but not limited to clinicians, biologists, clinical researchers and bioinformaticians. We provided an overview and some insights on how these TBI databases are used. The TBI databases are valuable resources available to generate, test or validate new hypothesis shiftily in a short amount of period. TBI databases continue to consistently contribute to the discovery and development of novel therapeutics and treatments. We believe in future there will be more TBI databases of high quality which integrates and brings together knowledge already acquired in the current TBI databases.

Electronic Health Record Integration

Hong Yung Yip, Nur A Taib, Haris A Khan, and Sarinder K Dhillon, University of Malaya, Kuala Lumpur, Malaysia

© 2019 Elsevier Inc. All rights reserved.

Introduction

An Electronic Medical Record (EMR) is a computerized system that contains a patient's health record generated in a medical practice. Its primary purpose is to integrate health care information to improve quality of care (Gunter and Terry, 2005). EMR systems are designed to store data accurately and to capture and reflect the state of a patient across time which includes records such as patient personal statistics and demographics, past medical history, diagnosis information such as laboratory test results, and surgery related information. The improved access of readily available healthcare information provides a well-coordinated, collaborative, and multidisciplinary care that contribute to better quality of healthcare delivery (Cutler, 2010). Traditionally, EMR data is designed and stored in relational database management system (RDBMS), since it offers a powerful declarative query language known as Structured Query Language (SQL) which is capable of handling complex queries. The limitations of the current implementation of EMR using relational model are presented in later section.

Data visualization is visual representation of data which is indispensable in order to convey message, facilitate understanding and discovery, make sense of complex data which assists users in analyzing and reasoning evidence (Aparicio and Costa, 2015). In the case of a clinical studies of EMR data, data visualization allows one to quickly identify areas requiring attention or improvement, identify relationships and patterns of a disease outbreak, pinpoint emerging trends, etc. (SAS, 2016).

Linked data is one of the use cases in visualization model. It is a method of publishing structured data so that it can be interlinked and become informative through semantic queries (Fig. 1). This technology has revolutionized the era of semantic web and defined a new way of how information can be traversed (Bizer *et al.*, 2009).

The primary objective of this study is to propose a novel way of visualizing and linking EMR data by developing a NoSQL graph database using Neo4j. With the same set of EMR data, this study also compares and contrasts the performance, in terms of query runtime and storage requirement between relational (Microsoft SQL Server) and NoSQL databases (Neo4j and MongoDB document-oriented database). Other criteria such as scalability, availability, consistency, data models and open source availability are also subjectively measured. Additionally, this study evaluates the differences between MS SQL Server and Neo4j in terms of schema design, ease of programming language, maturity and level of support, flexibility, and security to demonstrate how graph databases can provide a viable data storage and management alternative applicable to EMR systems.

Electronic Medical Record (EMR)

A system that handles operations and stores EMR records is referred to as an EMR system. Some of the benefits of an EMR system include efficient information sharing function to improve the value and quality of integrated health care to support development of health policies, medical education and advanced research (van der Linden *et al.*, 2009). However, despite its benefits, there are many obstacles and challenges in relation to EMR systems such as standardization of vocabulary, security, privacy and data quality. Nonetheless, Orfanidis *et al.* (2004) claimed that the one of the most critical issues with the current EMR systems is the ever expanding size of healthcare data. The exponential and uncoordinated growth of information systems in healthcare industry in terms of size and heterogeneity of data has resulted in no standardised data that makes, linking, retrieval and analysis difficult. Moreover, most EMRs are not customizable enough to cater to the information needs of researchers from different backgrounds. Fortunately, data visualization or visual analytics holds the potential to address the current information overload that is becoming more and more prevalent.

Data Visualization and Linked Data

Data visualization is the science of analytic reasoning which involves the study of the visual representation of data. It has revolutionized data sciences by enabling mapping, and visualization to allow better inferences of complicated data (Huang *et al.*, 2015). Proper visualization provides an alternative approach to illustrate potential data interconnectedness and relationships. Data visualization, despite having applied in various domains of healthcare (Huang *et al.*, 2015), remain absent from EMR data visualization using NoSQL graph model.

One of many use cases in visualization model involves Linked Data, which uses uniform resource identifiers (URIs), hypertext transfer protocol (HTTP) and resource description framework (RDF/JSON) technologies. Its importance include large scale integration of data on the Web (Bizer *et al.*, 2009). One of the best example of a large Linked Dataset is DBpedia, which utilizes the content in RDF format from Wikipedia to link to other datasets on the Web (W3C, 2015).

Table 1 Categories of NoSQL databases (Abramova and Bernardino, 2013)

Category	Description
Key-value store	Data are stored as key-value pairs or hashes. The unique keys are utilized to index and retrieve the information stored in values. Examples are Redis, Azure Table Storage and DynamoDB.
Document store	Document store is similar to key-value store, however, their values are typically documents in formats such as eXtensible Markup Language (XML) or JSON. This category offers great performance and horizontal scalability. The internal storage is similar to relational databases but more flexible due to the lack of schema. It is also great for storage since it does not store empty or null values.
Column-family	Data are stored in columns. Each key is associated with one or more columns. This category is suitable for data mining and analytic systems due to high scalability. Examples are Cassandra and HBase.
Graph database	Data are stored as graph in the form of nodes (objects) and edges (relationships). The primary goal is to visualize the relationships between nodes. Examples are Neo4j and InfoGrid.

Fig. 2 Comparison of three main data model types used in NoSQL versus relational databases in terms of CAP Theorem. Reproduced from Ercan, M.Z., 2014. Evaluation of NoSQL databases for EHR systems. In: Proceedings of the 25th Australasian Conference on Information Systems, pp. 1–10. Auckland, New Zealand.

Potential benefits of NoSQL databases for EMR systems

Table 2 describes the main requirements of an EMR system and how newer NoSQL database system features can address these requirements to develop a distributed healthcare system.

NoSQL graph database

Graph databases enable queries that allow semantic web technology to function with the data defined and represented by nodes, edges and properties. They data retrieval from complex data structures easily as compared to relational systems (Neo4j, 2016a,b,c,d,e). Contrary to relational databases that operate with SQL language, the difficulty with graph

Fig. 3 Three categories of CAP Theorem. Reproduced from Ercan, M.Z., 2014. Evaluation of NoSQL databases for EHR systems. In: Proceedings of the 25th Australasian Conference on Information Systems, pp. 1–10. Auckland, New Zealand.

Table 2 Comparison of EMR requirements and corresponding NoSQL database features (Ercan, 2014)

EMR requirement	NoSQL database feature
Size of healthcare data expanded over time and eventually became a bottleneck for traditional EMR systems.	NoSQL databases are based on horizontal scalability which permits effortless and automatic scaling.
Increasing heterogeneity of healthcare data such as free-text notes, images and other complex data that are unstructured or semi-structured require new storage alternatives.	Flexible data models or schemas powered by NoSQL databases allow complex data to be stored easily.
Healthcare records should always be accessible for undisruptive and continuity of healthcare services.	NoSQL databases provide high availability due to its distributed nature and data replication.
Healthcare records are normally added, not updated.	Eventual consistency of NoSQL database architecture provides an acceptable EMR use cases.
Sharing of healthcare data requires concurrent access to EMR systems from multiple locations which requires a high-performance system to respond to data access and retrieval request in a timely manner.	Contrary to relational databases, NoSQL distributed databases offer higher performance that is capable of spanning data across server nodes, racks, or even multiple data centers with no single point of failure.
Implementation and infrastructure costs are high.	Most NoSQL database systems are open-source and can run on inexpensive commodity hardware architectures.

database is that no query language has ever been standardized. Most graph based applications make use of application programming interfaces (APIs) for querying, though there are some query languages available like SPARQL and Gremlin (Wood, 2012).

Property graph model

Graph databases employ nodes, edges, and properties for data representation (Fig. 4). A node can hold any number of attributes or properties or key-value-pairs. Edges represent graphs or relationships, which are the lines that connect nodes to other nodes to describe relationship between them (Fig. 5).

Neo4j is the implementation chosen to represent graph database. Sponsored by Neo Technology, it is an open-source NoSQL graph database implemented in Java and Scala for all non-commercial uses (Vicknair *et al.*, 2010). Neo4j is an embedded, disk-based, fully transactional Java persistence engine that stores data structured in graph rather than in tables. It implements the property graph model with native graph storage and provides full database characteristics including ACID transaction compliance, cluster support, and runtime failover, making it suitable for the development of EMR database (Neo4j, 2016a,b,c,d,e).

Database and Database Management Systems (DBMS)

A database by definition, is a set of data and definition of its organization. It is an electronic collection of schemas, tables, queries, reports, views and other objects. A general-purpose DBMS provides functionalities to define, create, query, update and administer databases. DBMSs are often classified according to the database model that they support such as relational and

Fig. 4 The building blocks of the property graph model. Reproduced from Neo4j, 2016a,b,c,d,e. What is a graph database? Retrieved from Neo4j: <https://neo4j.com/developer/graph-database/>.

Fig. 5 Labeled property graph data model. Reproduced from Neo4j, 2016a,b,c,d,e. What is a graph database? Retrieved from Neo4j: <https://neo4j.com/developer/graph-database/>.

Table 3 Types of database languages (Beynon-Davies, 2003)

Language	Description
Data definition language (DDL)	Defines data types and their relationships.
Data manipulation language (DML)	Performs transactions such as insert, update or delete records.
Query language	Enables searching for information and computing derived information.

non-relational (NoSQL). Generally, a database is not backwards compatible through a range of different DBMSs. However, DBMS can be standardized to allow compatibility. Databases can be manipulated using one or more of the following languages (Table 3).

Case Study of a EMR Graph Model

EMR Document Database Development

The EMR NoSQL document-oriented database was developed using MongoDB. To convert and export the existing EMR relational database to MongoDB, a third party application, MongoDB SQL Server Importer (SQL2Mongo) (Tuldoklambat, 2012) was used to achieve such task. SQL2Mongo required the specification of the source destination and the target database, and then automatically converts SQL data types directly to JSON data types as JSON output. Subsequently, a database transaction was performed in MongoChef (MongoDB GUI) to ensure the imported database and tables were consistent with those created in MS SQL Server. A sample query was also executed to verify the database integrity and to ensure data reproducibility of both MS SQL Server and MongoDB.

EMR Graph Database Development

Contrary to MongoDB, to import data from MS SQL Server into Neo4j, it is essential to transform a relational database schema and model it as a graph prior implementation. Since Neo4j graph database revolves around property graph model, a graph schema (Figs. 6 and 7) was derived from the EMR relational model with the following guidelines (Neo4j, 2016a,b,c,d,e):

- Each *entity table* is a *label* on nodes
- Each *row* in the entity table is a *node*
- *Columns* on the entity table become node *properties*

Once the graph schema was established, EMR data and their appropriate tables were extracted and exported from MS SQL Server using the built-in SSMS data exporter interface in CSV format. Since Neo4j is a Shell-based application without GUI unlike MS SQL Server, all actions were performed using its native language, Cypher (Neo4j, 2016a,b,c,d,e). Cypher's LOAD CSV command was used to load the contents of the CSV file into Neo4j to generate a graph structure according to the derived graph schema (Figs. 6 and 7).

Fig. 6 Full graph schema of EMR database. A snapshot view of the red outlined graph schema is shown in Fig. 7.

Fig. 7 Closer view of graph schema of EMR database.

The resulting graph with a total of 231 unique labels and 190 relationship types with 22,869 nodes, 22,869 relationships and 23,680 properties was generated.

Neo4j EMR Data Visualization

A single EMR record was fully visualized in Neo4j with all its adjacent relationships defined to confer semantics of EMR data. The full visualization (**Fig. 8(a–c)**) includes EMR data ranging from:

- Patient personal identifying information
- Patient family history of cancer
- Past medical and surgical history
- History of presenting illness
- Clinical examination information such as cancer location, size and description
- Imaging examination information such as mammogram, breast ultrasound, CT scan and bone scan
- Biopsy examination such as core biopsy and excision biopsy of tumor tissue
- Histopathology
- Diagnosis and metastasis information
- Surgical relation information
- Follow up therapy treatment records

Fig. 9 illustrates a simple visualization of how patient demographics information can be linked with past medical history to allow meaningful data representation.

Discussion

Data Visualization and Linked Data

In relational databases such as MS SQL Server, EMR data is retrieved by the users according to a set of defined criteria. In such cases, the results will be limited to only what the user intended to query. EMR data contain extensive amount of information about a patient and metadata on how healthcare is delivered. However, Graph databases such as Neo4j provide visual representations to facilitate effective visualization renders to assist users in analyzing (Aparicio and Costa, 2015). According to Fig. 8(a-c), EMR data were well presented as a graph consisting of nodes interconnected with relationships to confer semantics for sense-making and data analysis. Fig. 9 illustrated a simple visualization of how patient demographics data were linked with past medical history in Neo4j.

Fig. 8 (a) Full visualization of a single EMR record in Neo4j.

Relational Versus NoSQL Databases

Performance of MS SQL server versus MongoDB

According to the results obtained, MongoDB was 4 times faster than MS SQL Server with an average execution time of 1ms to 4ms respectively in performing simple queries 1–4. Results were in agreement with comparative study conducted by [Parker et al. \(2013\)](#).

For the more complex query 5, involving multiple object types and nested queries, MS SQL Server had a runtime of 6 ms while MongoDB had a runtime of 11.75 ms. MongoDB was 2 times slower than MS SQL Server. MS SQL Server excels in join operations of relatively modest amount of structured data and SQL comes with native aggregate function like DATEDIFF(). In the present study, EMR records/ documents (Date of surgery) from one collection was first unwind to be copied/ joined to the second collection (Date of diagnosis), and subsequently underwent subtraction and division operations to calculate the time taken to surgery in days. This slows down the performance by a considerable amount. Unlike using SQL, MongoDB uses reference to locate

(b)

(c)

Fig. 8 (Continued) (b) The relationship between adjacent nodes in a record in Neo4j conferring semantics of EMR data. (c) Visualization of a record in Neo4j, showing the relationships between clinical symptoms and test carried out.

data in memory, additional decisions and aggregate functions such as lookup were required to determine how to implement or join relationships between collections, hence the slower performance (Parker *et al.*, 2013).

Performance of MS SQL server versus Neo4j

According to our results, MS SQL Server was 2 times faster on average compared to Neo4j with a mean execution time of 4.5–8.5 ms in performing simple queries 1–4. Results were in agreement with study by Vicknair *et al.* (2010). With regard to performance, Neo4j appears to have lower optimization features around querying for null values since it does not store empty or null values

Fig. 9 Simple visualization of patient demographics linked with past medical history in Neo4j.

natively (Neo4j, 2015). Query 1–4 involve conditions using CASE statement with SUM aggregate function to search through each and every record (total 99) to query for the total number of breast cancer cases and surgeries performed respectively. However, the Patient records retrieved in this case study were not fully populated and contain some empty values, hence the slower performance from Neo4j.

Since query test 1–4 were performed on default configurations, theoretically speaking, options such as memory allocation can be adjusted, tuned and optimized to improve input/output (I/O) and read/write performance. According to Vicknair *et al.* (2010), relational database performed better than Neo4j at small scale, but scaling upward dramatically shifted the search times in favor of Neo4j.

For the more complex query 5 which involves date and time notions, MS SQL Server had a runtime of 6 ms, whereas the test was not applicable to Neo4j as Neo4j currently does not have a native date/time/timestamp value type (Neo4j, 2015). Therefore, aggregate function to determine the date/time difference was not feasible in Neo4j. Neo4j is considerably new with only seven years of production. It is still undergoing active development.

Storage requirement of MS SQL server versus MongoDB

Database storage comprises of the internal (physical) level in the database architecture as well all the information needed such as metadata to construct the conceptual and external level. According to the results obtained, with the identical set of EMR data, MongoDB was 51 times more space-efficient than MS SQL Server, occupying only 0.50 MB in disk space compared to 25.50 MB in MS SQL Server. This can be attributed to differences in storage engine and the way the data is stored in MS SQL Server and MongoDB (Nguyen, 2010).

The storage engine manages the nature of how the data is stored in a database. MS SQL Server uses SYBASE storage engine. It is a full-featured engine but is generally slower due to its ACID compliance for reliability (VCU, 2013). Most of the data are stored in disk which explains the higher storage requirement. Read and write speed can also be bottlenecked by the performance of disk I/O. On the contrary, MongoDB comes with two supported storage engines: MMAPv1 (Memory Mapped Version 1) engine and WiredTiger storage engine (MongoDB, 2016a,b,c,d,e,f). MMAPv1 is MongoDB's original storage engine based on memory mapped files. It prioritizes memory usage over disk as its cache to read and write documents. In addition, WiredTiger is a newer storage engine that scales on modern multi-CPU architectures. It offers document level concurrency control with native compression to minimize on-disk overhead and I/O, which significantly reduces the amount of storage required by up to 80%, unlocking new infrastructure efficiency and cost savings (MongoDB, 2016a,b,c,d,e,f). Hence, the observed lower disk space consumption by MongoDB compared to MS SQL Server.

Storage requirement of MS SQL server versus Neo4j

According to the results obtained, Neo4j was 1.35 times more space-efficient than MS SQL Server, consuming only 18.87 MB to 25.50 MB in disk space. Likewise, the observed difference can be attributed to the variation in storage engine and the way how the data is stored.

Neo4j storage engine is powered by Neo Technology, which behaves similarly to MongoDB, where it prioritizes memory usage rather than disk with newer compression engine to read and write data. However, Neo4j is actually a fully transactional database with ACID compliance ([Neo4j, 2016a,b,c,d,e](#)), which explains the higher disk space usage compared to MongoDB.

Performance and storage scalability

The requirement of scalability for EMR systems is considered restrictive as most of the current systems are based on relational databases which are not designed to scale, which calls for a need of newer scalable database systems to maximize output at the expense of lower storage requirement ([Jin et al., 2011](#)). Based on the objective tests (performance and storage size) conducted in this study, it was noticeable that NoSQL databases such as MongoDB and Neo4j performed better with a lower disk space requirement compared to MS SQL Server.

To scale is to either increase hardware capacity or increase the amount of data stored per capacity. For an example based on results in, 25.5 MB was required to store 99 records in MS SQL Server, whereas 99 records occupied only 0.50 MB and 18.87 MB in MongoDB and Neo4j respectively. Therefore, with an effective similar storage size of 25.5 MB, MongoDB and Neo4j can theoretically store up to 5049 and 135 records, a 51 and 1.35 time increased in the amount of data stored per same capacity respectively due to newer storage and compression technology.

On the contrary, NoSQL database systems are based on shared-nothing approach where servers have their own dedicated resources such as RAM, processor or storage, allowing scaling horizontally ([Cattell, 2011](#)).

Availability

[Schmitt and Majchrzak \(2012\)](#) suggested that the nature of EMR data holds critical patient records which therefore, requires the prerequisites of having both high availability and distributed data management to allow the system to function even a single point of failure within it. Based on CAP Theorem, NoSQL database systems trade consistency for availability and introduce eventual consistency concept ([Dede et al., 2013](#)). In addition, data replications allow failovers to enable “always-on” database systems which is crucial to the day-to-day operations in hospital settings.

Consistency

NoSQL is not ACID compliant, instead it adopts BASE principles. In NoSQL databases, data read by clients immediately after being updated may be outdated as not all nodes have been updated instantly. Due to this though there is no guarantee of consistency at any instance of time, it eventually will be consistent at some point in time ([Vogels, 2009](#)). [Bailis and Ghodsi \(2013\)](#) showed that the inconsistency is less than a second and therefore, eventual consistency model is claimed to be adequate in most use cases. Due to this, weaker consistency models can therefore be applied using NoSQL databases in healthcare environment without the fear of causing any major setback in terms of data consistency ([Frank et al., 2014](#)).

Data models

The need to store heterogeneous medical data has increased since using relational databases has proven inefficient and difficult to handle and manage such data ([Jin et al., 2011](#)). NoSQL databases support various types of data structures which allow flexible modelling of data, contrary to relational databases which support only structured model.

Relational Versus Graph Databases

Schema design

Schema refers to the organization of data as a blueprint of how the database is constructed prior implementation. A schema design in relational model adheres to the notion of theory in predicate calculus to define tables, fields, relationships, views, and indexes ([Rybiński, 1987](#)). Hence, relational databases are limited to homogenous data structure and extremely ineffective for heterogeneous, unstructured and frequently changing data.

In a clinical setting, data collected from patient can be in the form of texts or images. According to relational databases, data structure must be homogenous. On the contrary, a new label can be easily defined and linked to store both text and image records since graph databases embrace relationships over data types. Therefore, in terms of handling multiple variants of data, graph databases like Neo4j are more suitable for the task as relational schema is more rigid and less flexible.

Language

Relational databases like MS SQL Server use SQL to query and manage relational data. It is based upon relational algebra and tuple relational calculus. It consists of a DDL, DML and Data Control Language (DCL). SQL is a declarative language which includes data insert, query, update and delete, schema creation and modification, and data access control. It is sub-divided into several language elements ([Table 4](#)).

Table 4 SQL language elements (ISO.org, 2011)

Element	Description
Clauses	Constituent components of statements and queries.
Expressions	Produce either scalar values, or tables consisting of columns and rows of data.
Predicates	Specify conditions that can be evaluated to SQL three-valued logic (3 VL) (true/false/unknown) or Boolean truth values that are used to change program flow and limit the effects of statements and queries.
Queries	Retrieve data based on specific criteria.
Statements	Control transactions, program flow, connections, sessions, or diagnostics.

Neo4j uses Cypher language which is a declarative graph query language that allows for expressive and efficient querying and updating of the graph store. It is a relatively simple yet powerful. Unlike SELECT statement, Cypher uses MATCH and WHERE. WHERE is used to add additional constraints to patterns. CREATE and DELETE are used to create and delete nodes and relationships. SET and REMOVE are used to set values to properties and add labels to nodes (Neo4j, 2016a,b,c,d,e).

Maturity and level of support

Relational database has been around for decades and is one of the most used systems. They are used in almost every commercial and academic pursuits and have spawned several commercial ventures such as Oracle and Microsoft. Relational databases benefit from having a unified language, SQL. Since SQL does not differ greatly between implementations, support for one implementation is generally applicable to other implementations. Graph databases on the other hand, have less market penetration in general. Since most of the graph database systems are open source, their commercial ventures are usually smaller and lack a unified language. Neo4j however, has a reasonable amount of support. Hence in terms of maturity and level of support, relational databases have a better edge.

Flexibility

Both relational and graph databases perform equally well in the environments for which they were designed. Flexibility measures how well they perform outside of those environments (Vicknair *et al.*, 2010).

MS SQL Server is a large server application designed to perform in a large-scale multi-user environment. While it is optimized, it may be too heavy weighted for small applications users as there some overhead for features that are not necessarily beneficial for the small user.

Neo4j is small, light-weight, and efficient. It performs well at server scale and does not impose the overhead often associated with server applications (Vicknair *et al.*, 2010). Unlike MS SQL Server which only works on Microsoft ecosystems like Windows, as a Java component, Neo4j supports cross-platform deployment, meaning it can be run on Windows, Linux or Mac OS (Neo4j, 2016a,b,c,d,e). Therefore in terms of flexibility, Neo4j graph database is the clear winner.

Security

Most relational databases in general such as MS SQL Server have extensive built-in multi-user support. Different privileges can be assigned to individuals or groups to grant different user views and actions. On the contrary, many graph databases including Neo4j lack much support for multi-user environments. It forces all user management to be handled at the application level. By extension, Neo4j assumes a trusted environment and does not have any built-in security support (Vicknair *et al.*, 2010). Relational databases such MS SQL Server are better at ACL-based security.

Limitations of Current Study and Proposed Future Work

The present study illustrated a full scale visualization of EMR data in Neo4j and demonstrated a simple use case of how records can be linked among EMR data. Future work can look into importing and integrating open data in RDF/JSON format with current EMR graph database system, Neo4j to study and assess the proposed idea of Linked Data initiative.

Future work shall look into assessing the scalability of NoSQL databases in terms of performance and storage in comparison to a relational database in various configurations and scenarios by using different size of EMR data. In addition, EMR data can be distributed among different nodes to evaluate the performance and horizontal scalability of NoSQL database systems in a distributed environment compared to a single system using relational database. Future work can also look into assessing availability of NoSQL databases by deploying and maintaining a number of replications to simulate failovers in the event of power or systems failure.

Conclusion

Electronic Medical Records store and manage huge amounts of clinical data. New approaches are needed in order to achieve higher performance and to store data efficiently than is possible with traditional relational databases. In this study, we demonstrated that NoSQL databases (MongoDB and Neo4j), particularly the graph model is a powerful tool to visualize EMR data for sense-making

and data analysis. Graph model allows one to identify make predictive inferences which are beneficial in qualitative research. Graph model stores data in JSON format, which can be easily linked with open data to create new relationships and extend information as linked data uses a universal interchangeable RDF/JSON format to describe things. Nonetheless, the capacity of graph model and linked data are underutilized due to the lack of adoption in healthcare domain.

This study also demonstrated that NoSQL databases such as MongoDB and Neo4j performed better with a lower disk space consumption compared to relational MS SQL server. Although we cannot conclude the clear superiority of NoSQL databases over relational database, we however provide enough reasons such as generic suitability and technical and financial reliefs for large scale data-intensive applications that is provided by NoSQL databases. Given the importance of EMR systems for healthcare delivery and overall health systems, distributed NoSQL databases arguable has a clear potential to dominate the development of EMR applications due to the scalability, high availability, and flexibility it provides.

Overall, this study demonstrated how graph database system such as Neo4j is the way forward due to its powerful visualization model and potential for linked data. Although it fell short in terms of maturity, level of support and security compared to relational databases, its flexibility in handling heterogeneous data with dynamic schema, SQL-like Cypher programming language and advantages as a NoSQL database provide a better data storage and management alternative viable to hospital EMR systems.

Genome Databases and Browsers for Cancer

Madhu Goyal, University of Technology Sydney, Sydney, NSW, Australia

© 2019 Elsevier Inc. All rights reserved.

Introduction

Researchers over the last two to three decades supporting the fact that different type of cancers are fundamentally a disease of the genome. Genes are being studied and identified that underlie the different types of cancer. A better understanding of these genes is one of the most pressing needs in basic cancer research. Huge amount of the genome sequence data has become available in the last two decades for researchers to do research on cancer. This explosion of data has also provided opportunity for researchers to identify patterns among data and to develop understanding the way cancer is caused by changes in the DNA, RNA, and proteins of a cell that drive over growth of cells. This big data has also witnessed the development of the systematic study of the cancer genome and sophisticated sequencing technologies. The knowledge of cancer genome databases is very important to guide the development of more effective approaches for reducing cancer morbidity and its mortality. The identification of the genomic variations that arise in cancer can also help researchers decipher cancer development and improve upon the diagnosis and treatment of cancers.

Cancer genomics data (Chin *et al.*, 2011) is complex and heterogeneous just like cancer itself. But a comprehensive analysis of the cancer genome still remains an overwhelming task. This is partly due to the limitations in current technologies to visualize, integrate, compare and analyze cancer genomics data. Such limitations prevent investigators from truly appreciating the breadth and depth of these genomics and epigenomes resources. Thus careful statistical and algorithmic considerations are required to integrate the information provided by the large volume and variety of data alongside clinical annotations. The specific conclusions extracted from data must be presented in a coherent system for display and analysis should be accessible to the scientific and medical communities.

Genomes databases (Schattner, 2008; Yang *et al.*, 2015) for Cancer contain the information of DNA sequence and gene expression differences between tumor cells and normal host cells. Genome database mean a data repository that includes all or most of the genomic DNA sequence data of one more organisms. Human genome database includes “annotations” that either describes the features of the DNA sequence itself or other biological properties of humans. The multiple fundamental tasks are involved in building a genome database, which include identification of the locations of the genes within the genome sequence, aligning transcript data into the genomic sequence, sequencing the genomic DNA and assembling the fragments of DNA sequence onto the length of chromosomes.

A genome database typically also includes a web based interface referred to as ‘genome browser’. Genome browsers have been created to allow the simultaneous display of multiple annotations within a graphical interface. They provide the ability to search for markers and sequences, to extract annotations for specific regions or for the whole genome and to act as a central starting point for genomic research. Genome browsers allow researchers to navigate the genome in an comparable way to navigating the internet e.g., with Internet Explorer, Mozilla Firefox or Chrome. Nowadays the amount of available genomic data is vast or big and different open source databases aim to make these data accessible to all researchers. The number and variety of annotations has increased dramatically and thus there is huge requirement of a detailed view of many aspects of the genomes. In this paper several popular cancer genomics data repositories and browser applications are described (Table 1).

Various genome databases and browsers have provided different analysis tools, which have proven to be successful at facilitating a better understanding of the genomes. The overwhelming amount of cancer genomics data from multiple different technical platforms has provided increasingly opportunities to perform data integration, exploration, and analytics, especially for scientists without a computational background. These cancer genomics resources have specifically lowered the barriers of access to the complex data sets and thereby accelerate the translation of genomic data into new biological insights, therapies, and clinical trials. They have offered researchers comprehensive repositories, contextual information, and curated data as a method of handling the exponentially growing amount of sequence data. Although these resources have been useful and have solved many issues, but they will continue to face new types and ever-growing amounts of data that will exacerbate many more challenges.

Systems and Applications

NCI'S Genomic Data Commons (GDC)

The NCI's Genomic Data Commons (GDC) provides the cancer research community with an integrated data repository that enables data sharing across different cancer genomic studies. The National Cancer Institute (NCI)'s Genomic Data Commons was previously managed by the Cancer Genomics Hub (CGHub), which was established in August 2011 to provide a repository to promote the sharing of cancer data, collaboration between cancer researchers, and to generate effective treatments for the Cancer. CGHub rapidly grew to be the largest database of cancer genomes in the world, storing more than 2.5 petabytes of data and serving downloads of nearly 3 petabytes per month. The Cancer Genomics Hub mission project was completed in 2016. The GDC supports several cancer genome programs at the NCI's Center for Cancer Genomics (CCG), including The Cancer Genome Atlas (TCGA) and Therapeutically Applicable Research to Generate Effective Treatments (TARGET).

Table 1 Key resources for cancer genomics research and study

<i>Name</i>	<i>Website</i>	<i>Key features</i>
NCI's genomic data commons (GDC)	https://gdc.nci.nih.gov/	Big data repository
Cancer genome atlas (TCGA)	https://cancergenome.nih.gov/	Big data repository

SomamiR 2.0	http://compbio.uthsc.edu/SomamiR	Database of cancer somatic mutations in microRNAs (miRNA)
canSAR	https://cansar.icr.ac.uk/	Open source, multidisciplinary, cancer database developed to make provision for cancer translational research and drug discovery
NONCODE	http://www.biinfo.org/noncode/	Database of cancer somatic mutations in microRNAs (miRNA)
China cancer genome database (CCGD)	https://db.cngb.org/cancer/	Large comprehensive genome database of Chinese cancer patients

The NCI's Center for Cancer Genomics (CCG) was established to command the NCI effort in generating, cataloging and unification of datasets of alterations seen in human tumors. It also aims to be at the forefront of supporting the development of analytical tools and computation approaches for improving the understanding of large-scale multidimensional data. The CCG supports several comprehensive cancer genome research programs including The Cancer Genome Atlas (TCGA) and the Office of Cancer Genomics (OCG). OCG includes two programs i.e., Therapeutically Applicable Research to Generate Effective Treatments (TARGET) program and the Cancer Genome Characterization Initiative (CGCI). TCGA, TARGET, CGCI, and other CCG programs have provided a complete characterization of genomic changes in several human cancers; however these characterizations are maintained in separate repositories, in diverse formats, and with different data management infrastructures. NCI established the GDC to unify these efforts and to provide the cancer research community with a data service supporting the receipt, quality

control, integration, storage, and redistribution of standardized cancer genomic data sets derived from various legacy and active NCI programs.

Cancer genome atlas (TCGA)

The Cancer Genome Atlas (TCGA) is the result of collaboration between the National Cancer Institute (NCI) and National Human Genome Research Institute (NHGRI). It has created a genomic data analysis pipeline that can effectively collect, select, and analyze human tissues for genomic alterations on a very large scale. It has also generated complete multi-dimensional maps of the key genomic changes in 33 types of cancer. The TCGA dataset of about 2.5 petabytes describing tumor tissue of more than 11,000 patients is publically available and has been used widely by the research community. The data have contributed to more than a thousand studies of cancer by independent researchers and to the TCGA research network publications. The success of this national network of research and technology teams serves as a model for future projects and exemplifies the tremendous power of teamwork in science.

GDC's data analysis, visualization, and exploration (DAVE) tools

DAVE is a web interface for intuitively exploring and analyzing GDC's cancer genomic data. It provides an unprecedented level of flexibility in exploring the data by selecting patients with particular altered genes or other relevant biological and clinical features. Researchers can navigate from project cohorts to individual patients, to specific genes and mutations of interest. The tool can generate specialized graphs to help researchers visualize the genes in which the most somatic mutations are observed. Users can also plot patient survival curves and identify the molecular consequence of a mutation on the resultant protein. All cases of the project can be plotted and visualize the top 50 mutated genes affected by high impact mutations in the GDC's OncoGrid.

ICGC Data Portal (DCC)

The primary goal of International Cancer Genome Consortium (ICGC) has been to catalogue and coordinate a large number of research projects that have the common aim of interpreting the genomic changes present in many forms of cancers. ICGC has generated huge data knowledgebase of genomic abnormalities (somatic mutations, abnormal expression of genes, epigenetic modifications) in tumors from 50 different cancer types and/or subtypes across the globe and make the data available to the entire research community. The ICGC's Data Portal provides tools for visualizing, querying and downloading the data released quarterly by the consortium's member projects. The ICGC facilitates communication among the members and provides a forum for coordination with the objective of maximizing efficiency among the scientists working to understand, treat, and prevent the different cancers.

cBio Cancer Genomics Portal

The cBioPortal for Cancer Genomics was originally developed at Memorial Sloan Kettering Cancer Center (MSK). The public cBioPortal site is hosted by the Center for Molecular Oncology at MSK. The cBioPortal software is now available under an open source license via GitHub. The cBio Cancer Genomics Portal ([Gao et al., 2013](#)) is an open-access resource for exploration of multidimensional cancer genomics data sets. It currently provides access to data from more than 160 cancer studies. The portal provides graphical summaries of gene-level data from multiple platforms, network visualization, survival analysis and also software programmatic access. The cBio Cancer Genomics Portal significantly lowers the barriers between complex genomic data and cancer researchers who want rapid, intuitive, and high-quality access to molecular profiles and clinical attributes from large-scale cancer genomics projects.

COSMIC

COSMIC ([Forbes et al., 2017](#)), the Catalogue of Somatic Mutations in Cancer, is the world's largest and high resolution resource for exploring the genetics of human cancer. COSMIC is a database that collects these somatic mutation data from a variety of public sources into one standard repository containing all forms of human cancer, from the most frequent cancers in lung, breast and colon, to extremely rare forms of blood cancer. Currently, COSMIC contains 1335 disease descriptions across more than 5000 detailed classifications. Its public website has been custom-built to make the many annotations in it which can be easily explored in user-friendly graphical ways whilst also providing large tabulated data sets. The front page of website offers multiple ways to explore the database e.g., 'Resources', 'Tools', and a range of pages describing the database content and details on its accessibility.

Cancer Program Resource Gateway

The central component of the Broad Institute's Cancer Program is Cancer Program Resource Gateway, which addresses unanswered questions of cancer genomics through platforms, datasets and resources. The institute was founded in 2004 due to the need that arose from the Human Genome Project to successfully decipher the entire human genetic code. This prestigious and famous institute is owned by MIT and Harvard and the main goal is to improve human health by using genomics to advance understanding and treatment of human diseases. The cancer program resource gateway has two strands i.e. data and tools.

Some of the popular resources are:

Cancer cell line encyclopedia

The CCLE (Cancer Cell Line Encyclopedia) project is collaboration between the Broad Institute, and the Novartis Institutes for Biomedical Research and its Genomics Institute of the Novartis Research Foundation. Its main objective is to conduct a detailed genetic and pharmacologic characterization of a large panel of human cancer models. The Cancer Cell Line Encyclopedia (CCLE) project is an effort to conduct a detailed genetic characterization of a large panel of human cancer cell lines. The CCLE provides public access analysis and visualization of DNA copy number, mRNA expression, mutation data and more, for 1000 cancer cell lines.

FireHose

In order to systemize the analyses from The Cancer Genome Atlas TCGA and to study the remaining diseases FireHose was developed. GDAC Firehose now sits atop ~55 terabytes of analysis-ready TCGA data and reliably executes thousands of pipelines per month.

FireBrowse

FireBrowse is a simple way to explore cancer data, backed by a powerful computational infrastructure, application programming interface (API) and graphical tools. It sits above the TCGA GDAC Firehose one of the deepest and most integrated *open* cancer datasets in the world with over 80 K sample aliquots from 11,000+ cancer patients, spanning 38 unique disease cohorts.

TumorPortal

TumorPortal is for analyzing and visualizing genes, cancers, DNA mutations and annotations. In TumorPortal datasets can be explored by tumor types as well as genes.

Integrative genomics viewer (IGV)

The Integrative Genomics Viewer (IGV) is a high-performance visualization tool for interactive exploration of large, integrated genomic datasets. It supports a wide variety of data types, including array-based and next-generation sequence data, and genomic annotations. Although IGV is often used to view genomic data from public sources, its primary emphasis is to support researchers who wish to visualize and explore their own data sets or those from colleagues.

Genome analysis toolkit

The GATK is the industry standard for identifying SNPs, DNA and RNAseq data. It also has the capability to find somatic variation, to tackle copy number (CNV) and structural variation (SV). GATK also includes many utilities to perform related tasks such as processing and quality control of high-throughput sequencing data. And although it was originally developed for human genetics, the GATK has since evolved to handle genome data from any organism

Hail

Hail is an open-source, scalable framework for exploring and analyzing genomic data. It can generate variant annotations like call rate, Hardy-Weinberg equilibrium p-value, and population-specific allele count. Hail can also generate new annotations from existing ones as well as genotypes, and use these to filter samples, variants, and genotypes.

European Genome-Phenome Archive

The European Genome-phenome Archive (EGA) is designed to be a repository for all types of sequence and genotype experiments, including case-control, and family studies. It includes SNP and CNV genotypes from array based methods and genotyping done with re-sequencing methods. EGA serve as a permanent archive that will archive several levels of data including the raw data (which could, for example, be re-analysed in the future by other algorithms) as well as the genotype calls provided by the submitters. Data at EGA is collected from individuals whose consent agreements to authorise data release only for specific research use to bona fide researchers. The EGA accepted data types include raw data formats from the array-based and new sequencing platforms as well as phenotype files describing study samples. EGA offers a range of tools for the file and meta-data upload like Java EgaCryptor, which encrypts and verifies all the accepted file types, and the EGA Webin portal for the metadata submission.

Network of Cancer Genes (NCG)

The network of cancer genes (NCG) is a web based tool to duplicability, orthology and evolutionary appearance of cancer genes. It introduces a more robust procedure to extract manually curated genes from published cancer mutational screenings. NCG allows to interpreting cancer sequencing by determining if a gene has already been reported as a driver gene in a given cancer type. This helps interpreting the mutational landscape of a tumor sample and to identify whether the genes mutated have a known role in cancer or if they are likely to be passengers. NCG provides new approaches to target cancer genes i.e., the systems-level properties reported for each cancer gene and allow identifying new targets and strategies to target a mutated gene.

MutaGene

MutaGene (Goncarencu *et al.*, 2017) is an online computational framework, which explores DNA context-dependent mutational patterns and underlying somatic cancer mutagenesis. It explores mutational profiles of cancer samples, identifies the combinations of underlying mutagenic processes including those related to infidelity of DNA replication and repair machinery, and various other endogenous and exogenous mutagenic factors. It also calculate expected mutability for each DNA and protein site using background mutational models.

UCSC Xena

UCSC Xena (Goldman *et al.*, 2015) is a cancer genomics browser for viewing, analyzing, visualizing the public data hubs of cancer genomics and clinical data. It is a web-based application that is developed in response to a crucial demand in the cancer research field for integrative visualization of large, complex genomic datasets arising from different technology platforms. It hosts many public databases such as TCGA, ICGC, TARGET, GTEx, CCLE, and others. These databases are normalized before use so that they can be combined, linked, filtered, explored and downloaded. Xena is very flexible with data and can load most types of genomic or phenotype data into it. Researchers can explore the relationship between genomic alterations and phenotypes by visualizing various genomic data alongside clinical and phenotypic features, such as age, subtype classifications and genomic biomarkers. It can also generate Kaplan Meier plot (KM plot) to test whether a genomic or phenotype variable significantly affects survival. Xena can group samples by any data (cell lines, xenografts, organoids, or patients) and then use these groups to compare expression or any other genomic data.

canEvolve

CanEvolve (Samur *et al.*, 2013) supports different type of analysis of information extracted from 90 cancer genomics studies comprising of more than 10,000 patients. The portal stores functional genomics and other large-scale data on cancer which includes gene, mRNA, microRNA and protein expression, genome variations and protein–protein interactions. The portal also provides stored knowledge in database (canEvolve web portal is implemented using MySQL open source system) as well as generate analysis results from oncogenomic profiles in response to user queries. It allows visualization of knowledge and analysis results in an appropriate manner and let the user download query results and related information from the portal. The querying for primary analysis includes differential gene and miRNA expression as well as changes in gene copy number measured with SNP microarrays. Finally, canEvolve provides query functionalities to fulfill most frequent analysis requirements of cancer researchers towards generating novel biological hypotheses.

MethyCancer

DNA methylation plays a vital role in the development of cancer and is associated with oncogene activation and chromosomal instability. MethyCancer (He *et al.*, 2008) hosts integrated data of DNA methylation, mutation and cancer information from public resources, and the CpG Island (CGI) clones derived from large-scale sequencing. The database also has graphical Methy-View, which shows DNA methylation in context of genomics and genetics data. It thus facilitates the research in cancer to understand genetic mechanisms that make dramatic changes in gene expression of tumor cells.

SomamiR

Genetic and somatic mutations or miRNA–mRNA interactions have been associated with various cancers. The miRNAs are small non-coding RNAs, known for their role as post-transcriptional regulators of protein-coding mRNAs. SomamiR 2.0 (Bhattacharya and Cui, 2016) is a database of cancer somatic mutations in microRNAs (miRNA). It helps researchers study the interactions between miRNAs and competing endogenous RNAs (ceRNA) including mRNAs, circular RNAs (circRNA) and long noncoding RNAs (lncRNA). It also has webserver miR2GO which is integrated with the database to provide a seamless pipeline for assessing functional impacts of somatic mutations in miRNA seed regions.

canSAR

canSAR (Tym *et al.*, 2016) is open source, multidisciplinary, cancer database developed to make provision for cancer translational research and drug discovery. It integrates comprehensive multidisciplinary knowledge i.e., annotation for genes, pharmacological, drug and chemical data with structural biology to enable target validation and drug discovery. It also applies machine learning approaches to provide drug-discovery useful predictions. It is known globally as the key resource to aid target selection and prioritization of drug discovery for cancer. canSAR thus provides unique views on genes and proteins, drugs, 3D structures, protein interaction networks, cancer cell lines and cancer clinical trials.

NONCODE

Mounting evidence shows that non-coding RNAs play key roles in various biological processes and in disease etiology. The recently reduced cost of RNA sequencing has produced an explosion of newly identified data, and as a result there has been an explosive rise in the number of newly identified non-coding RNAs. NONCODE (Yi *et al.*, 2015) is an integrated database of cancer somatic mutations in microRNAs (miRNA) from several species such as human and mouse. NONCODE provides a subset searching interface, literature support, other database support and long-read sequencing method support. The quality controls also include selection of exon numbers, the lengths of the transcripts and prediction tools support. The web interface presents the subset according to the conditions users chose and allow users to download the data.

China Cancer Genome Database (CCGD)

The China Cancer Genome Database (CCGD) is built by China National GeneBank as a first, large comprehensive genome database in China. The CCGD Data Portal stores, catalogs, and accesses the cancer related data, and provides a platform for researchers to download data sets. The types of data include raw data, clean data, alignment data, function analysis data, phenotype data. This database collects and stores cancer genome data and shares with all cancer research centers in order to promote the development of China cancer genome research. The database utilizes these data or research mechanism of the most frequently occurred cancers among Chinese population and largely promotes research of the early diagnosis and cure of cancer in China.

Conclusions

Advancement in software and information technologies has enabled software developers and bioinformatics researchers to integrate different publicly-accessible genetics data types from a large variety of sources. The coordinated efforts of many organizations have also led to the development of large-scale cancer genomics through which complete catalogs of the genomic alterations in specific cancer types can be obtained. Overall there are four different categories of genome resources discussed in this article. The first category represents very large repositories of genomics data such as TCGA, ICGC, COSMIC, EGA, cBio portal, China Cancer database with their own browsing tools. The second category resources offer tools for data analysis, data integration, and visualization (e.g., UCSC Xena, FireBrowse, TumorPortal, IGV, GATK, Hail, NCG, MutaGene). The third class includes databases that focus on inferring the association of specific biological features to cancer (e.g., MethyCancer, SomamiR, and NONCODE). Finally, databases such as CanSAR support the application of genomics to drug discovery. There are other useful resources for cancer research, but are not included in this paper due to the limitation of space and scope.

Although the methods for analyzing cancer genomes have improved at a swift rate, but still many challenges remain. Big Data management and advanced computational methods should be developed and integrated with tools to establish the clinical relevance of cancer genomic discovery. Collecting accurate clinical information on tumor samples remains an important and challenging task, but one that is necessary for the interpretation of genomic findings in depth. However, most available samples are associated with incomplete annotation or lack appropriate consent to permit the linkage of clinical information. There is thus a huge scope for personalized cancer genomic information, which once widely available and successfully implemented, holds considerable promise for improving the lives of many patients with cancer. Lastly, but importantly, the growing number of genome databases, analysis tools, and other resources available on the web has made it an unnerving task for researchers to use these resources effectively.

Introduction

With the digital revolution, there has been an explosion in the amount of information available, which in turn has transformed the traditional ways of data analyses. Mining important information from terabytes of data is the need of the hour. Data mining uses sophisticated algorithms and statistical measurements to extract useful information from existing data. In modern day computing, the main types of data are text, numbers and multimedia. Text mining is the process of analyzing a collection of unstructured data in the form of text and deriving useful information or generating a new hypothesis. There is a wide scope and application of this technology in risk management, cyber-crime prevention (Berry and Kogan, 2010; Witten *et al.*, 2016; Kontostathis *et al.*, 2010), fraud detection (Joudaki *et al.*, 2015), biomedical research (Rebholz-Schuhmann *et al.*, 2012), to name a few.

Text mining for bioinformatics has an overwhelming potential for translational research. There are thousands of research articles published every year showcasing the discoveries made in the scientific field, making it difficult for the researchers to follow them in great details. Due to the massive information generated, there is a need for computational tools to parse and analyze the information to make the learning process simpler. Text mining, as the term suggests, is the use of an automated method for extracting meaningful data from the wealth of information available in literature and other resources. The process of text mining comprises mainly of information retrieval, information extraction, knowledge discovery and hypothesis generation. The information extracted in the process is generally stored in database for future reference.

There are various tools and resources that are used by bioinformaticians for retrieving and extracting information from unformatted data. Some of the extensively used retrieval engines for biomedical research are PubMed, PubChem, RefMED, UK PubMed Central (Walport and Kiley, 2006), WorldWideScience, MedlinePlus, GoPubMed and Google Scholar (Ananiadou *et al.*, 2006). In order to extract information, some of the commonly used resources are iHOP, Textpresso, Open Biomedical Annotator, InAct, MedScan, Reactome as well as KEGG (Rebholz-Schuhmann *et al.*, 2012). There is a constant effort in building curated databases that contain information retrieved and extracted for specific purposes. STRING, STITCH, SIDER, HPID, HPRD, Bio-Caster, PharmGKB are few databases that have been curated and extensively used by researchers to conclude valuable inferences (Rebholz-Schuhmann *et al.*, 2012; Zhu *et al.*, 2013). Fig. 1 depicts the process of text mining involving converting unformatted text to machine-interpretable structured format.

Text mining is computationally intensive and is performed using technologies such as natural language processing, knowledge management, information extraction, machine learning as well as pattern recognition. The present text mining tools have virtually explored only the tip of the iceberg and there is still lots to be explored. The field of text mining has a wide scope for research development and has immensely assisted researchers in the advancement of biomedical research. Although, there are challenges associated with this field (discussed later), with the development of powerful algorithms and techniques, this field has received great impetus. This article discusses the fundamental concepts and various text mining resources developed for researchers.

Is Text Mining Ready to Deliver?

Information mining is a process that involves a clear understanding of various stages involved in parsing information. Some of these stages not only require bioinformatic techniques like pattern evaluation from databases and automatic detection, but scientific knowledge, analyst creativity as well as basic knowledge of the field. A better understanding of the biological process or problems help us to structure text mining projects, therefore, they are closer to accurate analysis rather than driven by chance or individual's insight.

History of Text Mining

Text mining techniques have evolved over many years with a view of expansion and improving methodologies by learning from previous attempts. Text mining was commenced in the earlier times to catalog the literature in the form of books in libraries. Soon, it was deviated to data retrieval using Natural Language Processing methods (abbreviated as NLP – it is an attempt to understand the modelling of the natural human language using computers). Indeed, text mining has evolved with time owing to improvised computational techniques. Since 2001, information on the internet has expanded from over 100 terabytes to 1500 terabytes in 2009, which is nearly 40% explosion in the information generation and storage. This exponential growth of information is mainly composed of a vast number of personal, public and corporate pages, news, electronic books, scientific data repository, databases *etc.* The Library of Congress, one of the largest library in the world contains 17 million catalog records for books, serials, manuscripts, maps, music, recordings, images, and electronic resources in its collections and is still growing exponentially. Although, this field is still in its developmental stage, it has already contributed to many scientific discoveries.

Fig. 1 Deconvolution of the unstructured data into machine-interpretable format using various text mining approaches.

Trends in Text Mining

In earlier days, library catalog involved text summarization and classification which was contributed by Thomas Hyde from University of Oxford for the Bodleian Library in 1674. Later in 1876, Melvil Dewey introduced the index card for library card catalog at Yale University. Text mining has not sprouted in one instance, rather several technological advancements, extensive data generations of different types and applications have contributed to the present modern data retrieving systems.

Later, by the year 1898, the text processing included summarization of the information for generating abstracts, majorly in Science stream (Luhn, 1958). It was as a joint collaboration between the Physical Society of London and Institute of Electrical Engineers. Luhn used computers to generate the document abstracts in 1958 by exploiting the word frequency analysis on an early IBM 701 vacuum tube computer (Luhn, 1958). It gave relative significance measurement of sentences which were combined according to their linear distances between the words to produce a metric of significance sentence contributing to form an abstract of a document. This automated procedure very well adapted in library sciences. Electronic versions of the scientific abstracts had become available since 1967 onwards.

As the technology advanced from huge room size computers to personal computers and revolution in digitization, document cataloging has improved with more access to other existing documents. Science Citation Indexing (SCI) is a citation index created by Eugene Garfield in 1964 from Institute for Scientific Information and is currently owned by Clarivate Analytics after Thomson Reuters. Its enhanced version Science Citation Index Expanded includes more than 8500 journals, across 150 disciplines (Garfield, 2006, 2007, 1964).

The searching mechanism was advanced by text manipulations, indexing, and development of Natural Language Processing (NLP). To access the information from the repository, two processes – Information Retrieval and Information extraction are used. Eventually, computational power in the 1960s invented NLP applications, clustering, information extraction and modern text mining methods. All these methods are briefly described in the next section.

Since 2000, major innovations and methods in text mining include modern information extraction engines (based on tokenization); categorization of text with Machine Learning techniques, Support Vector Machines, kernel-based learning methods, Neural Networks, automation, linking and statistical approaches (Miner, 2012). A glimpse of few of these methods are discussed in the next section.

Background

Mining information from big data repositories involves strategies and techniques that can process data in fast and reliable manner. In order to improvise scientific inferences and narrow down the search parameters, it is important to carry out pattern recognition, relation extraction, knowledge discovery as well as hypothesis generation. One of the major challenges of retrieving data from scientific databases demands the ability to think how such fundamental concepts apply to specific biological problems ([Sharma and Srivastava, 2016](#)). This section highlights the main concepts underlying textmining approaches.

Concepts

Text mining

The term denotes a process aimed at analyzing unstructured text extracted from various text resources, detecting lexical patterns useful for deriving previously unknown information ([Berry and Castellanos, 2008](#); [Sebastiani, 2002](#)).

Machine learning (ML)

It is a method to train computers to make and improve predictions based on given data without being explicitly programmed. Some of the widely used machine learning approaches are Hidden Markov Models (HMM), Support Vector Machines (SVMs), Conditional Random Fields (CRFs) as well as Maximum Entropy (ME) ([Sharma and Srivastava, 2016](#)).

Natural language processing (NLP)

It relies on machine learning algorithms to analyze and understand the context in human language that is easily interpretable by computers. NLP is used for text mining, translation, relationship extraction as well as speech recognition. This method involves processing of words in the text and relies on statistical techniques. Some of the open source libraries for NLP are Natural Language Toolkit (NLTK), Apache OpenNLP, Stanford NLP and MALLET (see “Relevant Websites section”).

Information retrieval

Information retrieval (IR) deals with searching for information as well as recovery of textual information from a collection of resources. The desired information is often posed as a search query, which in turn recovers those articles from a repository that are most relevant and matches to the given input. Google scholar, PubMed, UK PubMed Central [06] as well as Elsevier’s Science Direct are some of the widely-used document search and retrieval engines for research or publications. Also, resources like PubMed QUEST are very helpful in the rapid searching of PubMed for publications of interest ([PubMed, 1946](#)).

Information extraction

Information extraction (IE) is the task of automatically extracting meaningful semantic structures using different strategies and identify relations between concepts. Open Biomedical Annotator, iHOP, Textpresso, CoPub are examples of resources used for information extraction ([Rebholz-Schuhmann et al., 2012](#)).

Pattern recognition

It is a branch of machine learning and involves recognizing patterns in data and classify the input data into different classes based on certain features.

Document summarization

This tool takes the documents into consideration and returns a concise summary of the text that highlights key points in the longer text.

Importance of Text Mining

From Experiments to Articles to Models

The experimentalist designs and carry out the lab work (experiments) to obtain the results followed by its processing and interpretation. The significant outcomes are published in scientific journals that follow specific journal format comprising of Title, Abstract, Keywords, Text body, References, Tables and Figures.

National Center for Biotechnology Information (NCBI) developed PubMed database (see “Relevant Websites section”), which is an information retrieval system at National Library of Medicine (NLM). This database is mainly dedicated to life sciences literature. Access to the literature is through NCBI Entrez retrieval system which is a text-based search and retrieval method. It can have a search query by author name, the title of the papers, or the keywords.

Scientific community submits their citations electronically from different journals into PubMed. Presently, PubMed has more than 27 million citations for biomedical literature from MEDLINE, life science journals, and online books. Citations may include links to full-text content from PubMed Central and publisher websites. Among these published articles, few are indexed with

Fig. 2 The growth in indexed journals in PubMed (a) and recorded citations from 1965 to 2016 (b) is represented in plots. (https://www.nlm.nih.gov/bsd/index_stats_comp.html).

Table 1 A table illustrating the most used tools for text mining (Biological networks, Protein–Protein interactions, NMR/Crystal structure)

Database name [Reference]	Name of database	URL
NCBI-PubMed (Hanauer and Chinnaiyan, 2006)	Published biomedical literature	https://www.ncbi.nlm.nih.gov/pubmed
DIP (Salwinski <i>et al.</i> , 2004)	Database of interacting proteins	http://dip.doe-mbi.ucla.edu/dip/Main.cgi
HPID (Han <i>et al.</i> , 2004)	Human protein interaction database	http://wilab.inha.ac.kr/hpid/webforms/intro.aspx

STRING (Szkarczyk <i>et al.</i> , 2017)	Search tool for the retrieval of interacting genes	https://string-db.org/
PDB (Berman <i>et al.</i> , 2002)	Protein data bank	https://www.rcsb.org/pdb/home/home.do
UniProt (UniProt Consortium, 2011)	The universal protein resource	http://www.uniprot.org/

MeSH (expanded as Medical Subject Headings) term publication types to GenBank Accession numbers. MeSH is NLM curated medical vocabulary resource (see “Relevant Websites section”). MeSH, indexes and catalogues the terminology belonging to biomedical information (MEDLINE/PubMed and other NLM databases) in hierarchical order. The growth in the number of indexed journals in PubMed and recorded citations from 1965 to 2016 is represented in Fig. 2.

As discussed in concepts above, Google has developed Google Scholar search engine targeting academic and research users. It’s a scholarly literature that includes peer-reviewed papers, theses, books, abstracts, reports. On passing query it returns results based on full text, authors, publications types/journals and number of citations.

Biomedical literature has characteristics features in terms of usage of domain-specific terminologies (technical terms); words possessing ambiguity in their meaning e.g., *Drosophila* has genes named archipelago, capicua or ebony; new terminology and names, low frequency of certain words, typographical variants etc. to keep in mind while searching (Table 1).

Case Studies of Use of Text Mining in Bioinformatics/Biomedical Research

Accessing information from database: PlasmoDB as an example

Among the biological databases available for the scientific community, several dedicated databases exist belonging to a specific class, organism, characterization etc. For example – Eukaryotic Pathogen Database Resources, EuPathDB (see “Relevant websites section”) (Fig. 3) is a portal provided by Bioinformatics Resource Center for accessing genomic-scale datasets from wide eukaryotic microbes listed in Table 2.

This article will cover one of the databases from EuPathDB, called Plasmodium Genomics Resource, PlasmoDB (see “Relevant Websites section”) in detail (Aurrecoechea *et al.*, 2008).

Of the five species of Plasmodium- *Plasmodium vivax*, *P. falciparum*, *P. ovale*, *P. malariae* and *P. knowlesi*, mostly the first four species cause human malaria and occasionally by *P. knowlesi* which causes animal malaria. Among these *P. falciparum* is the most lethal. PlasmoDB comprises of all the updated information on each and every gene of these species/strains uploaded and submitted by the experimentalists. It has linked up the information to other relevant databases and summarized results in a single window.

The home page of PlasmoDB shows wide range of search options such as: text-based, gene models (exon count/gene type), annotations, curation and identifiers (gene IDs), genomic location, taxonomy (organism), sequence analysis (BLAST, protein

Fig. 3 Screenshot of EuPathDB.

Table 2 List of databases included in the EuPathDB consortium

Database	Url	Specification
AmoebaDB	http://amoebadb.org/amoeba/	Acanthamoeba, Entamoeba and Naegleria
CryptoDB	http://cryptodb.org/cryptodb/	Chromera, Cryptosporidium, Gregarina and Vitrella
FungiDB	http://fungidb.org/fungidb/	Agaricomycetes, Blastocladiomycetes, Chytridiomycetes, Eurotiomycetes, Leotiomyces, Oomycetes, Pneumocystidomycetes, Pucciniomycetes, Saccharomycetes, Schizosaccharomycetes, Sordariomycetes, Tremellomycetes, Ustilaginomycetes, Zygomycetes
GiardiaDB	http://giardiadb.org/giardiadb/	Giardia and Spironucleus
MicrosporidiaDB	http://microsporidiadb.org/micro/	Annaliia, Edhazardia, Encephalitozoon, Enterocytozoon, Hamiltosporidium, Nematocida, Nosema, Spraguea, Trachipleistophora, Vavraia, Vittiforma
PiroplasmaDB	http://piroplasmadb.org/piro/	Babesia and Theileria
PlasmoDB	http://plasmodb.org/plasmo/	Plasmodium
ToxoDB	http://toxodb.org/toxo/	Eimeria, Hammondia, Neospora, Sarcocystis, Toxoplasma
TrichDB	http://trichdb.org/trichdb/	Trichomonas
TriTrypDB	http://tritrypdb.org/tritrypdb/	Crithidium Endotrypanum, Leishmania, Trypanosoma
OrthoMCL	http://orthomcl.org/orthomcl/	Ortholog Groups of Protein Sequences

motif pattern, TF Binding Site Evidence), structure analysis (PDB 3D structures, predicted 3D structures, protein secondary structures), and micro-array expression based searches.

On looking in detail the results obtained after searching tyrosyl- tRNA synthetases by its Gene ID: PF11_0181, opens a page with a brief summary of the gene at the left side (**Fig. 4**): its name, type as in coding/non-coding, chromosome no. and its location, species and strain name.

Right panel reveals the experimental information, gene model- exons and transcripts with their length in pictorially; annotation, curations and identifiers – listing its previous IDs and alias notes that are specific to annotator or user comments; Link outs- external links to different databases and tools for the gene of interest (such as Entrez Gene, Gene DB, Malaria Literature Database, Ontology Based pattern Identification, PlasmoDraft, PubMed, UniProt); genomic locations on the chromosome; associated literatures to this gene/protein with their PubMed ID, DOI links, titles and authors; taxonomic classification- to which

Fig. 4 Screenshot of the PlasmoDB with tyrosine-tRNA ligase as a hit.

superkingdom, phylum, class, order, family, genus and species it belongs; Orthologous and paralogous list of proteins from different species; Synteny of this gene and its domains in pictorial form, phenotypic information, and genetic variation; transcriptomics expression information; sequences -protein/mRNA/genomic sequence and their lengths, structural information-structural homologous PDB IDs from different organisms, and structural information coverage of the protein; protein family classifications, signal peptides presence and its length and relevant BLASTP hits and low complexity regions, secondary structure predictions (Helix or Beta strands); functional classification, gene ontology classification, pathways involved and protein-protein interactions, proteomic- Mass Spectrometry based expression information at different stages of *Plasmodium falciparum* life cycle.

In addition, it allows to perform the multiple sequence alignment (ClustalW) or Multi-FASTA of the nucleotide sequence with any other set of sequences through external links. To conclude, this DB platform provides the best practices to retrieve all or any information of a gene/protein belonging to *Plasmodium* species.

Personalized medicine and text mining

Text mining has played a pivotal role in the development of diverse fields. The field of personalized medicine has immensely benefitted from development in text mining approaches. As shown in Fig. 5(a), the number of publications containing the term 'text mining' in title or abstract when queried in PubMed has increased greatly since 2001. We can forecast the number of publications for text mining from the trend of previous years. With rapid advances in genomics and healthcare, it has become possible to tailor the best medical intervention to an individual. With the knowledge of underlying genotypic variations responsible for a particular phenotype, we can improve predictions in turn leading to prevention and cure of disease. The field of personalized medicine is gradually becoming mainstream practice. With the options of genome sequencing and various health monitoring trackers, the field of personalized medicine has gained momentum. The field of text mining has immensely helped in deriving the relationships between various factors such as genes, proteins, metabolites and others. As can be seen in Fig. 5(b), the number of publications on personalized medicine is increasing every year.

Identifying the disease-gene relationship is a major challenge in this field. In many cases, ML-based methods are used to identify the genetic mutations described in biomedical literature related to particular disorder or disease. In one such study, the authors retrieved biomedical literature related to target disease and extracted information for mutation and disease (Singhal et al., 2016). They used several features such as statistical, distance and sentiment features for a ML-based method to predict the relationship between disease and gene mutation. The advantage of using this approach is generalizability and scalability as it is feasible to use the model to extract relationship for any disease using larger biomedical literature knowledgebase. Some of the

a)

b)

areas of improvement for text mining in personalized medicine is the availability of highly curated gene-mutation database, a crowdsourcing effort to curate existing databases, use of electronic health records and clinical trials data in addition to biomedical literature as well as robust methods for such analysis. Text mining and curation have facilitated biomedical research, development of knowledge base for precision cancer medicine being one of the relevant examples.

Cancer models and text mining

Cancer is responsible for deaths of millions of people every year in the world. There has been constant effort to find cure for cancer, and numerous publications feature cancer research each year. Biomedical text mining has been used by researchers in mining cancer-related genes and proteins and their relationship to various forms of cancer. Automatic recognition of relationship between cancer and genes or protein terms associated with the disease is one of the important aspects of bioinformatics. In order to identify genes related to prostate cancer and their relationship, prostate cancer-related abstracts from MEDLINE were used to develop maximum entropy-based system (Chun *et al.*, 2006). Other than identifying genes involved in cancer, it is also important to verify them. In one such study, the prostate cancer biomarkers obtained from experimental studies were validated by employing text mining approach with OMIM (Online Mendelian Inheritance in Man) (Deng *et al.*, 2006). One of the primary goals of cancer research is developing strategies for early detection of cancer so that it is useful for prevention and controlling the disease. Using biomedical text mining techniques, cancer risk assessment can be evaluated by using terms from literature as features, and developing classifiers for the purpose of automatic identification from text. Databases such as PubMeth, MeInfoText, and others are used for obtaining information such as genes and their association in cancer methylation (Ongenaert *et al.*, 2007; Fang *et al.*, 2011). Patient's clinical records also serves as a good source to extract relevant information. There has been great progress in creating automated systems for constructing models from free-text pathology reports. MedTAS/P is useful in mapping the pathology reports with cancer model (Codem *et al.*, 2009). This system also efficiently captures the details of grading and staging cancer. The clinical significance of such an NLP-based system is the ease in cancer practice management by sub-classifying cancer patients based on the grade or stage of cancer. This practice is slowly entering mainstream medicine and will be helpful to clinicians in deciding the course of treatment in near future. Some of the well-documented text mining systems used for clinical purposes are MedLEE (Medical Language Extraction and Encoding) system and cTAKES (clinical Text Analysis and Knowledge Extraction System) (Zhu *et al.*, 2013). Thus, to study the complex mechanisms of cancer, the need of the hour is text mining from hierarchical network view and discover new knowledge using this systems biomedicine perspective.

Text mining and drug discovery

Drug discovery is the process of identifying new candidate molecules that are selected by screening hits, their affinity, selectivity, potency, stability as well as bioavailability. The field of drug discovery has undergone a paradigm shift from using traditional methods to identify active ingredient to employing computational methods for such discovery (Bull *et al.*, 2000). Publicly-available chemical databases such as PubChem, Chemical Entities of Biological Interest (ChEBI), ChemExpr, ChemBank, Side Effect Resource (SIDER), ChemSpider, Therapeutic Target Database (TTD), and DrugBank provides information of chemical entities that can be explored for therapeutic purposes (Papanikolaou *et al.*, 2016). Text mining approach has been applied to extract information from DrugBank. DrugQuest is an information retrieval and extraction tool that uses textual information from DrugBank and clusters these records. Once the user provides query, the DrugBank records are selected on the basis of the fields such as the mechanism of action, pharmacodynamics, and indication. Named Entity Recognition techniques have been used for storing and parsing information from DrugBank. Tagging services such as Reflect and BeCAS (Papanikolaou *et al.*, 2016) help in minimizing the ambiguity in the gene, protein and chemical terms and are useful in resolving the issue of multiple synonyms while searching the text. The retrieved documents from DrugBank are clustered algorithmically on the basis of the information contained in them. DrugQuest efficiently summarizes the results of the analysis and also provides user the option of visual representation of the results. Although DrugQuest has the limitation of 5000 textual records per analysis, it takes only a few seconds to process and compute the output (Papanikolaou *et al.*, 2016). Fig. 6 shows the output obtained when 'isoniazid' and 'methotrexate' are given as query in DrugQuest.

Thus, text mining approaches are useful in mining chemical repositories to find relationship between chemical entities and leverage this information for drug repositioning. It will be even more useful if chemical information can be extracted simultaneously from various repositories such as PubChem, ChemExpr, ChEBI, and SIDER. This kind of concerted effort will boost the development of this field and provide information that was unknown till now.

Discussion

There is a surge of scientific data that is generated at an exponential rate and limited methods for comprehensive analysis of data. There is an urgent need for the development of searching methods to minimize the gap between powerful storehouses and fetching useful information in an efficient manner. User-specific problems have to be addressed primarily and in more structured way. Thus, an understanding of these facts is crucial for data scientists, recruiters, investors, or the end user scholars. A better and clear understanding of process and stages involved helps in our rationale and systematic thinking leading to less errors and their omissions.

There are challenges involved in searching methodology like human formulated questions using natural language – “What are the molecular functions of Glycogenin?”, alternative scientific terms, new terminologies derivations etc. Inferences derived using text mining resources can be of immense value to the scientific community as a whole. Indeed, there are evidences, claiming that data-oriented decisions and big data technologies improve scientific performances.

Fig. 6 The clustered output from DrugQuest for terms such as 'isoniazid' and 'methotrexate', respectively. Reproduced from Zhu, F., Patumcharoenpol, P., Zhang, C., *et al.*, 2013. Biomedical text mining and its applications in cancer research. *Journal of biomedical informatics*, 46 (2), 200–211.

Closing Remarks

Here we encourage the scholar to read listed references -published papers and books, relevant to the topic for advance information. Explore the information from given links of different bioinformatics databases and text mining tools. This will enable the learner to acquire the knowledge that is available while implementing it all together.

Introduction

Target identification is the first step in drug discovery. A target is an entity to which an endogenous ligand or a drug binds resulting in a change in its behavior or function. Enzymes, receptors and transport proteins along with DNA and RNA are the main targets for drugs at the molecular level. The pre-clinical drug development process is based on the hypothesis that modulation of the target(s) of interest will result in a therapeutic effect in a disease state. The human genome data is an excellent resource to understand the genetic factors in human disease, and one of its prime goals was to pave the way for new strategies for disease diagnosis, treatment and prevention; as it has the potential to reveal targets involved in a specific disease. However, not many new molecular entities have been discovered since the sequencing of the human genome. The paucity of translatable results can be attributed to several factors. Lack of accurate information on gene architecture and gene annotation which is essential for drug discovery as this allows insight into splice variants and drug cross-reactivity. Moreover, potential targets provided by the genome projects are not endowed with elaborate background knowledge because of our inability to infer the function of most of the DNA in the genome. Many of the computationally derived annotations in the databases are either minimal or incorrect (apart from a carefully manually-curated database such as Uniprot) (Zhao *et al.*, 2007). Also, as the annotation of genes is provided by multiple public resources using different methodologies, the resultant information may be similar but not always identical (Kangueane *et al.*, 2015). This is further confounded by our limitation to infer the number of splice variants or protein-protein interactions from gene sequences alone, thereby limiting our analyses of genome and in consequence, our estimation of the total number of targets. Lack of information on protein structure, protein function and binding of a specific drug to the target of interest adds another dimension to this puzzle. In conclusion, the increased number of targets and the lack of functional knowledge about them are generating a bottleneck in the target validation process (Ofra *et al.*, 2005). Despite the relatively limited knowledge about the complex relationship between chemical space and genomic space, drug development strategies have been influenced profoundly by the wealth of potential targets offered by genome projects (Finan *et al.*, 2017). This article highlights some of the key aspects in human pre-clinical drug target identification and validation.

Target Identification *in Silico*

Over the past two decades, several computational (*in silico*) methods have been developed and applied to generate pharmacology hypotheses. These *in silico* methods are primarily used alongside *in vitro* data to create the *in vivo* model for pre-clinical testing and optimization of novel molecules with the potential to bind to a target, and the ADMET (absorption, distribution, metabolism, excretion and toxicity) properties in addition to the physicochemical characterization.

Drugs Databases and Drug Target Databases

The first step towards drug discovery is the correct identification and validation of the drug target and its interaction with the drug. The key drug databases and drug target databases are:

Drug databases

The PubChem database contains about 35 million compounds. It is estimated that <7000 compounds have the information on their corresponding target proteins (Chen *et al.*, 2016). It has been reported that the known chemical space probably contains on the order of 100 million molecules and the estimate for Lipinski virtual chemical space is around 10^{60} compounds or a more modest 10^{20} – 10^{24} molecules if the combination of known fragments are considered (Ertl, 2003). ChEMBL contains 1.6 million distinct compounds, 14 million bioactivities, 11K biological targets, and other related data organized in 72 tables manually collected from the published literature. These data are very useful for drug discovery and include binding, functional and ADMET (i.e., assessment of *in vivo* absorption, distribution, metabolism, excretion and toxicity properties) information for a larger number of drug-like bioactive compounds (Nowotka *et al.*, 2017). ZINC contains over 120 million compounds for ligand discovery and virtual screening and allows for investigators to seek chemical matter for their biological targets (Sterling and Irwin, 2015). DCDB (Drug Combination Database) offers data on drug combinations. Its current version comprises of 1363 approved or investigational drug combinations, including 237 unsuccessful drug combinations, involving 904 individual drugs, from > 6000 references

(Liu *et al.*, 2014). The information about drugs and their targets is manually annotated based on the literature and relevant databases such as Drugbank (Wishart *et al.*, 2017), PubChem, UniProt and Drugs.com.

Thus, even with today's computational resource, the entire chemical space cannot be exhaustively enumerated computationally and prioritisation and targeted selection is essential for virtual screening.

Drug target databases

The DrugBank database is a richly annotated bioinformatics and cheminformatics resource that combines detailed drug data (e.g., chemical, pharmacological and pharmaceutical) with comprehensive target information (e.g., sequence, structure and pathway) (Wishart *et al.*, 2008). Therapeutic target database (TTD) provides the information about known and explored therapeutic protein and nucleic acid targets, the targeted diseases, pathway information and corresponding drugs directed at each of these targets (Chen *et al.*, 2002). Recently, the information of 1755 biomarkers for 365 disease conditions and 210 drug scaffolds for 714 drugs and leads has been added into this database (Qin *et al.*, 2014). PharmGKB is another pharmacogenomics knowledge resource that encompasses clinical information including dosing guidelines and drug labels, potentially clinically actionable gene-drug associations and genotype-phenotype relationships. PharmGKB also collects curates and disseminates knowledge about the impact of human genetic variation on drug responses (Thorn *et al.*, 2013).

Computational Approaches in Drug Target Identification

In order to understand the cellular processes taking place in response to a drug, it is critical to elucidate its molecular targets. This has tremendous implications for disease prevention and treatment. Here, it is important to mention that the incorrect identification of targets is a significant factor in drug failures and the low drug approval rate during drug development stemming from an incomplete knowledge on the underlying physiology of the target and incorrect biological hypothesis (Vasaikar *et al.*, 2016). Specifically, in line with this, the association of a drug with additional targets beyond its direct ones, may give rise to hazardous side effects, precluding further drug development and usage. 82% of Food and Drug Administration (FDA) approved drugs have an assigned mechanism-of-action (Overington *et al.*, 2006). However, at least half of the drugs with unassigned mechanism of action date from the pre-molecular era and have no targets defined as their action was explored against whole tissues, rarely on isolated proteins, and target identities were only inferred from tissue-based responses (Gregori-Puigjane *et al.*, 2012). Even though the total number of predicted drug targets of pharmacological interest is estimated in the range of 6000–8000 in the human genome, drugs have been approved for only a fraction of these targets (Landry and Gies, 2008; Plewczynski and Rychlewski, 2009). This is because a large number of these putative drug targets remain to be validated. Druggability is the presence of protein folds (quaternary structures) that favor interactions with drug-like chemical compounds (Hajduk *et al.*, 2005). The ability of a protein to bind a small molecule with the appropriate chemical properties and binding affinity might make it druggable, but does not necessarily make it a potential drug target. This is true, though, for proteins that are linked to human diseases (Hopkins and Groom, 2002). In this regard, Hopkins and Groom have highlighted that ~10% of the entire human genome is involved in disease onset or progression, resulting in ~3000 potential targets suitable for therapeutic intervention (Perumal *et al.*, 2009; Sakharkar and Sakharkar, 2007; Sakharkar *et al.*, 2007). An attempt to identify the number of druggable disease genes using DGIdb database (see "Relevant Websites section"), which is a compendium of 3860 druggable genes from BaderLabGenes, CarisMolecularIntelligence, FoundationOneGenes, GO, GuideToPharmacologyGenes, HopkinsGroom, MskImpact, RussLampel, and dGene resources and the DisGeNet platform which reports on the gene disease associations derived from expert curated databases and text mined data (see "Relevant Websites section") shows that there are 1645 druggable disease genes which are associated with 923 diseases. Here, it is important to mention that DisGeNet provides information on 26,522 disease gene associations reporting 7878 disease genes and 6761 unique diseases. Taking genes involved in breast cancer from BCDB database and mapping them onto the 1645 druggable genes, we found 471 genes that are involved in breast cancer and are druggable (Fig. 1).

Once the disease mechanism is understood and the target and lead compounds are identified, chemoinformatic tools present a tremendous potential to help decipher the interactions between protein targets and the ligands before expensive and time-consuming experiments. Towards this end, we have earlier shown the coffee component HHQ as a putative ligand for PPAR gamma and its implications in breast cancer *in vitro* (BMC Genomics) (Fig. 2) (permission applied).

However, one should keep in mind that the identification of novel drugs and their targets is still an extremely difficult goal owing to the limitation in mapping drugs and targets in chemical space and genomic space into a unified space, called pharmacological space.

Approaches for Target Validation *in Silico*, *in Vitro* and *in Vivo*

Validation is a crucial step in the drug discovery process. The only way to be completely certain that a protein is instrumental in a given disease is to test the idea in clinical trials. With the evolution of sequence targeted therapeutics like CRISPR and RNAi silencing, gene expression levels can be raised or lowered at transcriptional, translational or post-translational stages. The effects of these can be evaluated in preclinical models generated by the gene editing of experimental animals and human cells (2017). Additionally, the role of Genome-wide association studies (GWAS) of disease predisposition, metabolism and gene expression provides data on

Fig. 1 Schematic representation of number of genes involved in breast cancer as provided by breast cancer data base (BCDB). Out of 1645 druggable genes, 471 genes were involved in breast cancer.

functioning of protein-targeting drugs. GWAS also use the regulatory variation in human genomes to guide the therapeutic future of targeted gene regulation (2017). Thus, the protein based concept of druggability needs to be expanded and redefined. Several resources and techniques help validate the predicted drug-target interaction. Some of them are briefly described below:

Gene and protein expression profiling datasets: Gene expression profiling through transcriptomics (RNA profiling) and proteomics (protein profiling) has contributed significantly to our efforts in understanding complex biological processes. Technologies such as microarrays, quantitative real-time polymerase chain reactions, and next-generation sequencing have helped decipher the targeted receptor(s), pathway or network through the identification of downregulated or upregulated pattern(s) of the intended drug target (s). **Connectivity Map (CMAP)** is a publicly accessible gene expression database that contains over 1.5 million gene expression profiles from ~5000 small-molecule compounds, and ~3000 genetic reagents, tested in multiple cell types (see "Relevant Websites section"). CMAP collates, compares and links all changes in gene expression ("signatures") arising from a disease or gene modulation (knockdown or overexpression of a gene), or treatment with a small molecule (Lamb *et al.*, 2006). Differential expressions that show highly similar or dissimilar, expression signatures are termed "connected". Similar physiological effects on the cells imply that the transcriptional effects are related. GEO is a database of gene expression profiles derived from over 100 organisms and more than a billion individual gene expression measurements addressing several biological issues such as disease states and stages of development. It is a public repository that freely distributes this information that is submitted by the scientific community. It can be explored, queried, and visualized using user-friendly Web-based tools. **DeSigN** is a web-based tool for predicting drug efficacy against cancer cell lines using gene expression patterns (Lee *et al.*, 2017). It can use gene expression analyses to identify candidate drugs using an input gene signature. Identifying distinct common pathways/gene modules that are shared by pathophysiological processes of multiple diseases is made easier by the integration of these diverse datasets.

Phenotypic Screening

Phenotypic screening is based on the alteration(s) of metabolically active systems such as tissues or whole animals produced at physiological or molecular structural levels upon exposure to a chemical entity. Hits are identified in phenotypic screening and followed by the leads thereof by structural activity relationship assays. Phenotypic screenings are based on the system suitability, the stimulus and the end-point readout rather than the pathological and clinical endpoints (Vincent *et al.*, 2015). These ensure robustness, repeatability and cost-effectiveness of the procedure. Phenotypic screenings are carried out using test systems which include cell lines, situ organ/tissue preparations and animal models. The animal models used in phenotypic screening include *C. elegans*, *Danio rerio* (Zebrafish), *X. laevis*, and *Drosophila melanogaster*. In disease models, phenotypic screening involves the determination of changes in structural morphology and biochemical characteristics and effects of compounds (drugs) on reversal of the changes. The screening of compounds on the neurite growth and amyloid- β , neurofibrillary tangles in Alzheimer diseases

[B] Represents hydrogen bonds (in black dotted line) observed for HHQ (in yellow) with the active site residues in the ligand binding domain of 2PRG. [C] Represents superposition of the best conformation of Rosiglitazone (in red) and HHQ (in yellow) in the ligand binding domain of 2PRG. Rosiglitazone is a known ligand of PPAR γ (published in [Shashni, B., Sharma, K., Singh, R., et al., 2013](#). Coffee component hydroxyl hydroquinone (HHQ) as a putative ligand for PPAR gamma and implications in breast cancer. BMC Genomics 14 (Suppl. 5), S6).

and measurements is one of the best examples for phenotypic screening in which both the cellular morphology and the biochemical changes and effects of drugs are studied in parallel.

One of the key limitations of phenotypic screening is that it usually provides very little information on the possible targets of the compounds. Moreover, compounds with a poor ADMET may not be active in primary screens. These factors demand cell-based assays or transgenic/knockout models to identify the target proteins and provide some information on the possible mechanism of action of the compounds/drugs.

Transgenic organisms

Genetically modified animals are widely in research to create models of human diseases. These animal models are created based on a molecular understanding of genomic/proteomic alterations in human diseases. However, the intensity of up- or down-regulation, progress and intracellular accumulation may vary phenotypically from the human disease. Animal models are genetically modified to over-express (transgenic), remove ("knock-out"), or replace ("knock-in") specific genes. These animals are widely used to understand the pathology and investigate the effects of hits/leads for their efficacy ([Bolon, 2004](#)). Furthermore, the use of genetically modified models provides information on target identification and helps establish the precise mechanism efficacy or toxicity of the new chemical entities or drugs. For example, in the transgenic mouse model of Parkinsonism, the animals were modified to over-express human α -synuclein, a major protein that aggregates in neuronal cells in Parkinson's disease (PD). This animal model mimics PD pathology and simulates it closer to the human disease. Further, the animals which over-expressed human α -synuclein showed decreased dopamine turn over in turn motor deficits. Thus, the model serves as a target for the phenotypic screening of drug candidates having effects on α -synuclein. Transgenic models also help to rule out the down- or upstream signalling pathways, which are further helpful in understanding how the disease progresses and its possible therapeutic options.

Imaging

Imaging techniques have often been used to study gross anatomy. Read outs usually show structural deformities. With advancements in technology, it became feasible to image physiological and biochemical events in metabolically active systems such as cell lines and animal models. This is called functional imaging. The live imaging of specific proteins or target proteins of interest was made possible with the help of the development of molecular probes, this is often called molecular imaging. The main advantages of molecular imaging are that it is repetitive, non-invasive, and the effects are quantifiable at cellular and sub-cellular levels. These imaging techniques use various energy forms to penetrate or interact with the endogenous proteins or fluorescence tagged proteins in in-vivo systems (Fig. 3).

With the help of sophisticated imaging techniques, the identification of marker proteins and effects of drugs on the target proteins is performed in phenotypic screening. This helps to screen huge numbers of compounds at fast rates and more economically in drug discovery processes. Molecular imaging techniques are also being used to study the pharmacokinetics of drug following its administration. On the other hand, in vivo imaging techniques serve as an important tool for studying the pathophysiology and efficacy of drug on the reversal processes in an evidence based manner. As mentioned earlier, the use of molecular imaging became is a pivotal method in preclinical oncology research, including the xenograft and orthotopic models. For example, in a mouse lymphoma xenograft model, the effect of temozolomide on tumor progression and the prolongation of survival was studied. The tumor cells were transfected with the luciferase gene, enabling the visualization of lymphoma cells using bioluminescence (BL) imaging. The tumor growths between untreated and treated groups were studied with reference to the luciferase imaging (Kadoch *et al.*, 2009).

Biomarkers: Biomarker assays not only assist in patient selection and the design of clinical trials but also act as indicators of drug efficacy, toxicity and disease progression (Ganesalingam and Bowser, 2010).

This substantially increases their importance in drug discovery processes. These assays are initiated in cell lines and primary blood cells or isolated tissue cells and are used to validate in vitro modulation of target by the drug and the effect of drugs on cells that is routine cellular screening. Typically, these assays are initiated in human cell lines, primary blood cells or isolated tissue cells. Biomarker assays are also used to identify markers of drug sensitivity that are used in selection of patient populations. Biomarker assays for pharmacokinetic/pharmacodynamic (PK/PD) models have also been developed, profiling molecules prior to testing in longer term disease models as initial proofs of concept. PK/PD models can also assist in dose-to-man scaling predictions for use in clinical trials. The biomarker assays developed during the in vitro discovery phases are frequently used as efficacy or toxicity endpoints in the clinic. Clinical trials, particularly in oncology, are frequently designed around these biomarkers.

Fig. 3 Armamentarium of molecular imaging techniques employed to quantify target proteins. Nuclear imaging, magnetic resonance imaging, ultrasound imaging, and optical imaging techniques have been categorized as repetitive and non-invasive molecular imaging techniques.

Conclusions

Target identification and validation is costly and labour intensive. Failures in clinical trials are likely to have multifactorial reasons. However, selecting the most biologically plausible molecular targets that are relevant to the disease state is a critical first step to improve the probability of success. Towards this end, it is key to get a complete picture of the target(s), their role in a biological process and how they can be modulated to achieve the required output.

1 Introduction

The vast majority of biomedical knowledge is conveyed and shared by means of written text, ranging from publications in journals and conferences, summary abstracts such as those stored in PubMed (PubMed, 2016), notes in electronic health records, drug labels, or short descriptive entries in biomedical databases (Chatr-Aryamontri *et al.*, 2015; Dowell *et al.*, 2009; Eppig *et al.*, 2015; The UniProt Consortium, 2012; Van Auken *et al.*, 2012). As text is typically provided in the form of natural language sentences, searching for and gleaning information conveyed within requires much human labor or computational tools that can sift through text and identify relevant words or passages. Developing and applying such tools for processing text and finding relevant information is typically referred to as Text Mining. This is a broad area of activity and research, involving several disciplines. A key discipline is natural language processing (NLP), and specifically information extraction (IE). It focuses on obtaining structured information from natural-language text, by identifying certain entities (e.g., genes, proteins, or diseases) and relations between them (e.g., phosphorylation, activation, repression) mentioned within the text. The entities and the relationships are typically converted into a standard form, such as ontological terms or numerical identifiers, and stored in a database. Ontological terms are terms listed within a controlled and carefully maintained vocabulary that denotes entities pertaining to a certain domain, along with relationships among these entities. The Gene Ontology (GO) is the most widely used ontology in the biological domain (Gene Ontology, 2016; The Gene Ontology Consortium, 2000), while the Medical Subject Headings (MeSH) is one of several controlled vocabularies used in medicine, covering organs, symptoms, diseases, and other conditions (MeSH, 2016).

Another major text mining task is the identification of publications or text passages that are relevant to individual users or user-communities. Examples include papers discussing gene expression in the mouse, which are of interest for curation by the Mouse Genome Database (Eppig *et al.*, 2015), or papers indicating side effects of a drug – which may be of interest to individual physicians. The latter may also be of interest for curation by the FDA (The United States Food and Drug Administration). This area of text analysis is known as information retrieval.

Another area related to information retrieval is that of text classification. It can be viewed as another way of identifying documents relevant to specific tasks; however, rather than viewing the goal as that of satisfying the different needs of an individual end user, the objective is to partition a collection of articles into individual subcategories based on topics of interest. For instance, one may partition documents into those that are relevant to breast cancer, those that pertain to prostate cancer, and those that are not relevant to any type of cancer. Each relevance-category is called a class, and the objective is to label each document by its appropriate class. Clearly, there are many ways to classify documents into different categories, and as such, text classification is applicable in a variety of contexts, and used for a wide range of text-related tasks.

Throughout this module we provide background about these different text-related tasks, along with examples of their application within the biomedical domain.

2 Natural Language Processing and Information Extraction

As noted above, biomedically-relevant text is available from many sources and repositories, ranging from sentences and comments stored as annotations, to curated genes, proteins or processes, to complete publications stored in publishers databases and in

PubMed/PubMed-central (2016). To effectively seek information within text, computational methods that perform NLP are often used (Jurafsky and Martin, 2009; Manning and Schütze, 1999).

2.1 Basic Concepts and Challenges in Natural Language Processing

Consider an application that tries to automatically seek information about a specific protein within text. Basic processing of the text's natural language requires first identifying orthographical features including word breaks, word-capitalization, and punctuation marks, which help identify words, phrases, or tokens within sentences (Tokens are character-sequences that are treated as a single unit, a word, or a term; the task of identifying them is known as tokenization). Fig. 1 shows an example of a sentence, along with the components comprising it. The example demonstrates the value of orthographic information for identifying specific entities of interest; the names of genes/proteins like *FSP27* (Fat Specific Protein 27) and *PLIN1* (prelipin 1) are typically shown as a short sequence of capital letters followed by a number.

Notably, orthographic rules are not hard-and-fast; while they serve as useful cues for identifying word boundaries in general, as well as genes and proteins in the biological domain, capitalization is often used for a variety of other purposes, indicating abbreviations, acronyms, or the start of a sentence. Similarly, hyphens, dashes, periods and other delimiters can serve a variety of purposes. The multiple roles such features play within a sentence make the identification of components a nontrivial task.

Another indicator of a word's meaning is its morphology, that is, its structure as a composition of smaller common units. For instance, the words *interaction*, *interacts*, and *interacting* all share the same root form *interact* and the same semantics, where the differences are relegated to the suffix. Conversely, certain suffixes can be used to convey a common semantic meaning, for example, the suffix “*ase*” often denotes an enzyme (e.g., *kinase*, *ligase*). Thus, morphological analysis including suffix stripping or suffix detection can be useful in identifying words that denote certain entity types or convey a similar meaning – such as enzymes, diseases, drugs, or interactions among these entities.

The meaning of a phrase or a sentence depends on relationships among words and the role of each word within a broader context. Breaking the sentence into its components – known as parsing, and identifying the role of words – known as part of speech (POS) tagging, are both fundamental steps in NLP. Fig. 1 illustrates the syntactic parsing of an example sentence, and the assignment of POS tags to its components: *FSP27* and *PLIN1* are both nouns, *interacts* is a verb, *in* and *with* are prepositions. The set of POS labels used in practice is much more comprehensive (see for instance the *Penn Treebank corpora* (Marcus et al., 1993), that include tens of thousands manually annotated sentences, employing tens of POS different tags).

Similar to the dependency of each word's meaning on its neighboring words, the meaning of a sentence as a whole also depends on surrounding sentences. That is, the meaning of any sequence of words or sentences is context-dependent. Discourse analysis (Afantenos et al., 2010; Jurafsky and Martin, 2009; Conrath et al., 2014; Dascalu, 2014) is an area within NLP focusing on the meaning conveyed within broader text regions through relations among multiple sentences.

Seeking the actual meaning conveyed in the text through NLP is a complex and challenging task. A key obstacle to understanding natural language, by a computer or by a human being, is ambiguity. Ambiguity manifests itself in every level of the language. Orthographical cues have multiple interpretations where capitalization can indicate a beginning of a sentence, a proper noun, or an acronym. At the word level, a single word may convey multiple meanings (polysemy, e.g., the word *fly* may serve as a noun denoting an animal or a verb denoting the flight action); at the sentence-level, syntactic ambiguity occurs where a sentence may be parsed in more than one way conveying different intentions. Much work in NLP is dedicated to overcoming ambiguity, providing accurate tools for identifying terms within text, tagging and parsing sentences, and identifying types of discourse (see e. g., (Jurafsky and Martin, 2009; Manning and Schütze, 1999; Shatkey and Craven, 2012) for details and examples).

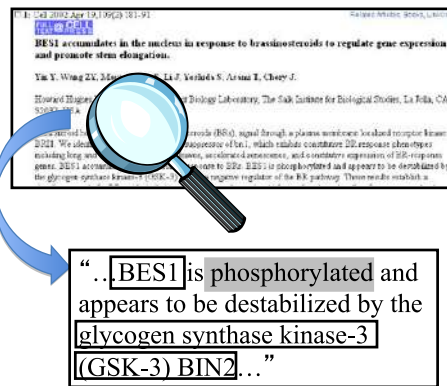

Fig. 1 A sentence (S) taken from a biomedical abstract (Grahn et al., 2014), along with its parse tree that shows parts-of-speech tags. Phrase tags, NP, VP, and PP correspond to Noun-, Verb-, and Prepositional-phrase respectively, while terminal tags – one layer above the bottom of the tree – indicate nouns (N), verbs (V), prepositions (PREP), and adjectives (ADJ). The leaves of the tree are the *terminals*, i.e., the words comprising the sentence.

A) Unstructured Data: Text from a publication

B) Structured Data: Phosphorylation Table

Kinase	Protein
<i>A-ase</i>	<i>P1</i>
<i>B-ase</i>	<i>P2</i>
...	...
...	...
...	...
<i>glycogen synthase kinase-3 (GSK-3) BIN2</i>	<i>BES1</i>
...	...

Fig. 2 (A) A biomedical paper (Yin et al., 2002) – shown as free, unstructured text (top), and a sentence within it discussing phosphorylation (bottom). (B) A structured phosphorylation table, showing a list of proteins and the kinase that phosphorylates each. The entry shown toward the bottom of the table is populated through information extraction methods applied to the sentence shown in A (bottom, left). The names of the identified protein and kinase are shown in dark frames, while the verb indicating phosphorylation is shown in gray.

The accuracy of NLP tools often depends on the domain in which they have been developed and employed (Ferraro et al., 2013; McClosky et al., 2010). Thus, as a basis for building NLP tools in the biological domain, specialized NLP resources providing annotations and tagging of biomedical sentences have been developed (Tateisi et al., 2005; Thompson et al., 2017) along with specialized tools for language analysis, for example (Cardie, 1997; Ferraro et al., 2013; Kang et al., 2011; Smith et al., 2004).

2.2 Information Extraction: From Unstructured Text to Structured Data

Two specific tasks that are often addressed within NLP and are of special interest within the biomedical domain are named entity recognition and relation extraction. The former means identifying mentions of relevant biological entities like genes, proteins, chemical compounds, drugs, diseases and many others; the latter refers to detecting relationships among these entities, such as reduction in drug efficacy due to a gene's activity, or interaction between two proteins or between two drugs. Gleaning such information from unstructured text and placing it in a database or within another structured format is known as IE (Cardie, 1997; Cowie and Lehnert, 1996).

Fig. 2 shows an illustration of IE applied to a text abstract. The task is the identification and extraction of phosphorylation relations between a kinase and a protein. The Protein and the Kinase entities are both identified, along with a verb that indicates a phosphorylation relationship. The entities are then harvested and placed in an entry of a structured phosphorylation table.

Named entity recognition is clearly needed for relation extraction (as illustrated in Fig. 2). It is also an important step toward indexing documents based on their contents so that documents discussing particular topics can be easily found, as discussed in Section 3.1. As such, much work in the field of biomedical text mining focuses on named entity recognition. It ranges from developing tools for gene- or protein-name extraction (Fluck et al., 2007; Leser and Hakenberg, 2005; Settles, 2005; Tanabe and Wilbur, 2002) to chemical- drug- or disease-identification (Batista-Navarro et al., 2015; Krallinger et al., 2015; Kuhn et al., 2016; Leaman et al., 2013; Lowe and Sayle, 2015; Savova et al., 2010). These methods rely on matching word-patterns to dictionaries containing curated entity-names, as well as on rules and machine learning methods, which are designed to distinguish named-entities from other words and terms. Extraction work is also being conducted in order to identify relations and statements pertaining to drug-interaction or other relationships among biological entities, for example (Kolchinsky et al., 2010; Kuhn et al., 2016; Savova et al., 2010; Comeau et al., 2014; Howe et al., 2016).

Notably, extraction efforts aim to identify explicit names and statements within text that contains relevant information. Identifying the publications and text passages that are indeed relevant to a certain subject matter is a task known as information retrieval, which is discussed next.

3 Information Retrieval and Text Classification

Information retrieval aims to identify a set of relevant documents in a large body of text. Commonly used search engines, like Google or PubMed, perform information retrieval known as ad hoc retrieval. The basic search mechanism in this case relies on a query specified by the user, where the query consists of a search term or a Boolean combination of terms. The search engine scans the large document collection and retrieves all documents that satisfy the query. The documents are then displayed in an order that is based on certain criteria such as temporal order, relevance, importance, or the number of citations.

Boolean term-combinations can be a cumbersome way to express a query, often resulting in many false-positives and false-negatives. A complementary form of ad hoc retrieval relies on similarity queries, within what is known as the vector space

(Manning and Raghavan, 2008; van Rijsbergen, 1979; Salton, 1989; Sparck-Jones *et al.*, 2000). Under this framework, a set of terms or words – which can even be a complete document – constitutes the query. The latter is represented as an algebraic vector in high-dimensional space; the vector is then compared against the text collection by employing a vector-similarity measure. The documents retrieved are those whose vector representation is most similar to that of the query vector.

Another aspect of information retrieval is text classification (e.g., Sebastiani, 2002; Yang and Liu, 1999). Rather than issue queries against the whole collection, the documents are split into different categories, where each category corresponds to a topic of interest. For instance, the categories may be defined a priori, where a collection of medical publications can be partitioned based on the disease discussed; here documents discussing kidney disease form a separate class from those discussing pneumonia. Categories may also be automatically uncovered by the categorization system, a process known as clustering. Throughout the rest of this section we discuss several mechanisms supporting the different types of queries, and provide examples for their use.

3.1 Boolean Queries and Index Structures

The basic mechanism that enables most information retrieval engines and Boolean queries in particular, is the index. As noted earlier, any document is initially processed by breaking it into its constituent terms, which can be individual words (also called unigrams), pairs of consecutive words (bigrams), longer sequences of consecutive words (n-grams), or grammatical phrases. An index is a data structure mapping each of the terms to all its occurrences within documents in the text collection. An illustration of an index structure is shown in Fig. 3. A Boolean query is executed by scanning through the index structure for the query terms and identifying the documents that satisfy the required Boolean combination of term occurrences (Manning and Raghavan, 2008; Witten *et al.*, 1999).

The basic index structure contains terms occurring in the document collection. However, other terms denoting fundamental concepts can be associated with the documents and included in the index. These may include, for instance, terms from the National Library of Medicine's MeSH controlled vocabulary (MeSH, 2016) assigned by human curators to documents, or terms from the GO (Gene Ontology, 2016; The Gene Ontology Consortium, 2000) that indicate properties of the proteins mentioned in the publication.

Boolean queries, expressed as terms connected by Boolean operators, (e.g., "BRCA1 AND Cancer") are supported in a straightforward way by index structures as shown in Fig. 3, albeit in their basic form can be ineffective for satisfying domain-specific information needs. Their limitations stem primarily from the inherent ambiguity of natural language as discussed in Section 1. Firstly, many terms occur often in a very large number of documents, thus the set of documents satisfying a simple Boolean query is too large for a user to practically scan through. Secondly, a query term typically has multiple meanings, varying by context (e.g., expression has a different meaning in the context of "gene expression" vs. "facial expression," while fly in the context of "fruit fly" carries a different meaning than in the context "birds fly"). Thus a large portion of documents that satisfy the literal query may end up being irrelevant to the user's actual need. Thirdly, documents that are relevant but use different words from the ones mentioned in the query (e.g., synonyms of the query terms) to denote the same idea, are not retrieved.

The vector space model, discussed next, offers an alternative mechanism, relying less on explicit or specific words and more on the whole context and the semantics denoted by words and phrases.

3.2 Similarity Queries: Documents in Vector Space

Naturally, we think about and visualize documents as sequences of words, terms, or sentences. As a step toward applying computational methods to text, we abstract away from our own use of documents, and view both documents and queries as

Fig. 3 An example of an index structure. The term entries in the index (right) are sorted alphabetically, and each term entry references the documents in which the term appears. Such a structure supports fast query processing, as documents containing the query terms can be quickly identified and accessed.

formal mathematical entities represented as algebraic vectors of weights, where each weight reflects the significance of an individual term. That is, every document d is represented as an N -dimensional vector of term-weights $\langle w_{t_1}^d, \dots, w_{t_N}^d \rangle$, where $t_1, \dots, t_N$ are the terms in the vocabulary and $w_{t_i}^d$ is a weight reflecting the significance of term t_i within the document d or the set of documents. A query q is likewise represented as a vector $\langle w_{t_1}^q, \dots, w_{t_N}^q \rangle$.

The retrieval task thus amounts to finding the document-vectors most similar to the query vector. Such queries are supported, for instance, by PubMed (PubMed, 2016) – where one can click on the link “Similar articles” next to a retrieved article and obtain links to all articles that share similar words or contents. Similarity-based retrieval methods vary across the specific choice of terms included in the vocabulary, the weighting scheme used to assign weights to these terms, and the similarity measure employed for comparing the vectors.

A simple weighting scheme is to assign a binary value (0 or 1) to each term, corresponding to its presence or absence in the document. Other weighting strategies are often applied, guided by several intuitive principles (Sparck-Jones *et al.*, 2000): (1) A term occurring frequently within a document, is typically important in the document’s context, and its weight should reflect this. (Local Term Frequency); (2) A term occurring in a very large number of documents typically does not characterize any specific document, and as such is less significant (Inverse Document Frequency); (3) A term occurring a few times in a short document is more significant to the document than if it occurs the same number of times in a long document (Inverse Document Length).

Weighting schemes that employ these principles thus include Local term frequency – the number of times the term occurs in the document, and variations on what is known as TF $\times$ IDF (Term Frequency $\times$ Inverse Document Frequency); the latter is a product of some function of the Local term frequency and the inverse of the number of documents within the collection that contain the term. Detailed weighting scheme strategies are discussed in the information retrieval literature (Manning and Raghavan, 2008; Salton, 1989; Sparck-Jones *et al.*, 2000; Witten *et al.*, 1999; Wilbur and Yang, 1996), where (Wilbur and Yang, 1996) is particularly relevant to the biomedical literature.

Once documents and queries are represented in vector space, vector-similarity is calculated to assess similarity between pairs of documents or between a query and each document in the collection. A commonly used vector-similarity measure is the cosine coefficient, which is the cosine of the angle between two vectors. For vectors $V_1 = \langle w_1^1, \dots, w_N^1 \rangle$ and $V_2 = \langle w_1^2, \dots, w_N^2 \rangle$, it is calculated as: $(\sum_{i=1}^N w_i^1 \cdot w_i^2) / (\|V_1\| \cdot \|V_2\|)$, where $(\|V_1\| \cdot \|V_2\|)$ are the norms of the vectors V_1, V_2 , respectively.

Several approaches, discussed next, take advantage of the vector model, using it to group together articles that share a common topic or theme. Some of these approaches use it directly, while others utilize a probabilistic interpretation of the weight-vector.

3.3 Text Categorization: Classification, Clusters, and Topic Models

One way to obtain documents that are relevant to a specific area of interest is to pre-categorize documents by such areas. For instance, as illustrated in Fig. 4, documents can be grouped according to the disease or other medical subjects of interest discussed in them. When a user looks for documents relevant to such a subject or area, all documents that are categorized as belonging to this area can be retrieved and returned.

A variety of machine learning methods are applied to address this task (Cohen and Singer, 1999; Dumais *et al.*, 1998; Joachims, 1998; Lewis, 1998; Lewis *et al.*, 2004; Sebastiani, 2002; Xu *et al.*, 2016; Yang and Liu, 1999). We distinguish between two types of categorization approaches: supervised categorization, known as classification, and unsupervised, known as clustering. In classification, the set of class labels is fixed and a set of pre-categorized documents, regarded as training examples, is available. A classifier is learned from the training examples, where the goal is to correctly assign class labels to documents outside the training set. Clustering, on the other hand, aims to identify subsets (clusters) of interrelated documents within the dataset, while separating unrelated documents into disjoint clusters – without having any predefined labels or pre-categorized training examples. Much of the categorization work done in the biomedical domain is concerned with supervised learning, i.e., classification. The methods that are often used in practice include decision trees (Mitchel, 1997; Quinlan, 1993), their extension to Random Forests (Breiman, 2001), naïve Bayes (Mitchel, 1997; Lewis, 1998; Sohn *et al.*, 2008), support vector machines (SVMs) (Joachims, 1998; Vapnik, 1995) and logistic regression (Schütze *et al.*, 1995; Vlachos and Craven, 2010).

Text categorization is based on the idea of similarity, where documents that are similar according to a certain similarity criterion are grouped together, while those that are dissimilar are placed in separate categories. In Section 3.2 we have discussed the vector representation for documents, along with the cosine similarity measure. This measure can be applied both in the

Fig. 4 Automatic text categorization. Documents are processed and assigned to a specific category based on their contents.

context of query-answering and for categorization. Another interpretation of the vector model views each weight w_i^j of a term t_i in a document d^j as reflecting the probability of the term to occur in the document. Under such probabilistic interpretation, the information retrieval task amounts to finding documents that with high probability satisfy the information need expressed by the query. Probabilistic models of retrieval have been introduced by Van Rijsbergen and others several decades ago (van Rijsbergen, 1977; Sparck-Jones *et al.*, 2000), and were further developed and formalized as language models (Ponte and Croft, 1998) and, more recently, as topic models (Hofmann, 1999; Shatkey and Wilbur, 2000; Blei *et al.*, 2003; Blei, 2012). Under a simple language model, we view a document as though it was produced by sampling terms from a language, where the language is modeled as a multinomial distribution over terms. Within the language-model framework, similarity between documents is expressed as their probability to have been generated by the same language model. A theme or a topic model (Shatkey and Wilbur, 2000; Blei *et al.*, 2003) extends the basic model, by having documents viewed as sampled from a mixture of several multinomial distributions, where the mixture defines a combination of subjects that are discussed within the same context. Some of the early work on theme models was developed specifically for analyzing biomedical literature, aiming to support gene-expression interpretation and enrichment-analysis for certain genomic functions (Shatkey and Craven, 2012; Shatkey and Wilbur, 2000). A more in-depth discussion of probabilistic, language and topic models can be found in the literature cited above as well as in more comprehensive books (van Rijsbergen, 1979; Manning and Raghavan, 2008; Shatkey and Craven, 2012).

Within the biomedical domain, much work on text categorization is concerned with supporting biomedical data-curation for public databases. For example, organism-specific databases including the Mouse Genome Informatics databases maintained by the Jackson Lab (Dowell *et al.*, 2009; Eppig *et al.*, 2015), WormBase (Van Auken *et al.*, 2012) and others, store information about gene expression or the effects of genetic mutations in the respective organisms. The information is obtained by curators who scan the relevant literature. Automatically identifying the relevant body of literature is a text-categorization task: a set of documents relevant to a specific database forms a class, while irrelevant documents form another class. Curators for databases that store information about proteins, their properties, and their interactions, such as BioGrid (Chatr-Aryamontri *et al.*, 2015), IntAct (Kerrien *et al.*, 2012) or UniProt (The UniProt Consortium, 2012) face a similar challenge. Such categorization of documents by relevance, is also known as triage, and has been the focus of work and shared tasks within the biomedical text mining community (e.g., Hersh *et al.*, 2006; Hirschman *et al.*, 2012).

4 Biomedical Applications, Shared Tasks, and Current/Future Challenges

We have already touched on several text-based methods applicable in biomedicine. This section provides a brief overview of text-related tasks that have been addressed and text-based methods that have been applied in biology and medicine – both early and recent.

4.1 Information Retrieval and Extraction Tasks

In terms of information retrieval, PubMed (2016) is the most comprehensive and widely used biomedical text-retrieval system. It supports Boolean queries, similarity queries, as well as refinement of the retrieval task utilizing pre-classification of the articles by species (e.g., Human, Other Animals), publication type (e.g., Review, Clinical Trial), and additional categories of common interest. Other large broadly-used biomedical data resources, such as the protein database UniProt (The UniProt Consortium, 2012), support text-based Boolean queries, which provide access to annotated entries based on the text description and GO terms associated with these entries.

Much other information-retrieval work involves text categorization. For example, identifying articles discussing mouse genomics is a text-categorization task supporting mouse-related curation. This task was one of the first text-related shared tasks, as further discussed below (Hersh *et al.*, 2006; Hersh, 2008). Other examples of text categorization include identifying documents and sentences discussing protein-interaction or protein-characterization (Denroche *et al.*, 2010; Donaldson *et al.*, 2003; Kolchinsky *et al.*, 2010; Krallinger *et al.*, 2011; Xu *et al.*, 2009), adverse drug reaction (Duda *et al.*, 2005; Sarker and Gonzalez, 2015), and many others.

In terms of fine-grained extraction and NLP, a lot of effort has been dedicated to identifying bio-entities – genes, proteins, drugs, chemicals and diseases, and on finding statements that link between such entities. The very first applications of text mining in biology (Leek, 1997; Blaschke *et al.*, 1999; Craven and Kumlien, 1999), specifically looked to identify protein names within sentences searching for statements of protein–protein interactions (Blaschke *et al.*, 1999), and for locations of proteins within the cell and location of protein-coding genes on the chromosome (Craven and Kumlien, 1999; Leek, 1997). This pioneering work was followed by much research and progress, improving gene- and protein-name identification (Fluck *et al.*, 2007; Leser and Hakenberg, 2005; Settles, 2005; Tanabe and Wilbur, 2002), and the recognition of other biomedical entities and relationships (Comeau *et al.*, 2014; Friedman, 2009; Hunter *et al.*, 2008; Kolchinsky *et al.*, 2010; Krallinger *et al.*, 2015; Kuhn *et al.*, 2016; Leaman *et al.*, 2013; Lowe and Sayle, 2015).

4.2 Community Challenges and Shared Tasks

The growing interest in systems that utilize text resources within biomedicine, along with the importance of assessing their utility toward meeting biologically-relevant challenges, has given rise to several shared tasks. In such shared tasks, a text-related challenge is proposed to the community by the challenge organizers, and teams come together to address the challenge. A gold standard

consisting of expert-annotated document sets is made available to the community, and the systems that are being developed are trained and tested over the provided datasets. The latter are typically formed by a well-recognized organization that maintains and curates large biomedical data resources, while the annotators are typically biologists, database-curators or physicians who have much expertise and experience in the relevant area. Performance measures that enable quantitative evaluation of the systems are also decided on as part of the challenge definition. While standard performance measures – accuracy, precision, recall, and variations over them are often used (see e.g., (Shatkey and Craven, 2012), Chapter 5.1), certain tasks require developing specific performance evaluation metrics.

The first shared task on biological text mining was introduced as part of the KDD-cup 2002 (Yeh *et al.*, 2002), where the challenge involved identifying evidence for gene expression in the fruit fly. This event was followed by several series of long-term organized tasks. One series, TREC-Genomics (Hersh *et al.*, 2006; Hersh, 2008; Roberts *et al.*, 2009) was introduced as part of the well-established text retrieval conferences (TREC) sponsored by the U.S. National Institutes of Standards and Technology (NIST) (TREC, 2016). It focused primarily on ad hoc retrieval (that is, addressing a variety of user queries), particularly searching for documents discussing specific aspects of genes and proteins (e.g., gene function, role in disease, expression within certain tissue types). TREC-Genomics was followed by additional TREC medical/clinical tracks for addressing retrieval from electronic health records and support clinical decision-making (Simpson *et al.*, 2014; Voorhees and Hersh, 2012).

Another important series of shared tasks, BioCreative (BioCreative, 2016; Hirschman *et al.*, 2005), focuses primarily on biological text mining in support of database curation. Aiming to facilitate Critical Assessment of IE in Biology, BioCreative has been running regularly since 2004, presenting challenges ranging from identifying named-entities such as genes or chemicals (Krallinger *et al.*, 2015), through finding evidence for protein–protein interactions (Krallinger *et al.*, 2011) to creating effective interfaces for textual annotation by curators (Wang *et al.*, 2016; Hirschman *et al.*, 2012). As high-quality ground-truth text annotations are essential for both training text mining systems and for assessing their performance throughout the shared challenges, using crowd-sourcing for obtaining reliable annotations is an important recent direction that is being studied as part of biological text mining (Hirschman *et al.*, 2016). Additional recent area-specific shared tasks include the i2b2 (Informatics for Integrating Biology and the Bedside) NLP tasks (i2b2, 2016), BioNLP challenges (BioNLP Shared Task, 2016) primarily affiliated with the Association for Computational Linguistics, and BioASQ (BioASQ, 2016; Tsatsaronis *et al.*, 2015) targeting question-answering and extraction of certain types of information from text records or the literature. Additional information about such shared tasks can be found recently published survey on the topic (Huang and Lu, 2016).

4.3 Knowledge Discovery Through Text and Future Directions

The basic form of automated text mining revolves around finding within the text facts and assertions that have already been uncovered and published. However, a highly useful and less conventional way of leveraging published text is by identifying indirect links that expose hitherto unknown information, giving rise to new knowledge.

Swanson's pioneering work (Swanson, 1986; Swanson, 1990; Swanson *et al.*, 2001) introduced the idea of uncovering new links between concepts or entities, by following indirect connections among them. A canonical example illustrating the idea was his showing that Raynaud's syndrome can be treated by increasing the intake of fish oil (Swanson, 1986). To do so he pointed out two separate recurring statements in the literature: (1) fish oil can reduce blood viscosity and (2) Raynaud's syndrome is characterized by increased blood viscosity. While no previous publication stated these two facts together, Swanson established the connection, noting the overlapping concept blood viscosity occurring in both the context of fish oil and the context of Raynaud's syndrome. He thus proposed that fish oil may be used for treating Raynaud's syndrome. The idea is illustrated in Fig. 5. Following Swanson's uncovering the putative connection between fish oil and Raynaud's treatment, an independent clinical study

Fig. 5 Example of a relationship discovery by connecting two indirect link. Swanson established a hitherto unknown relationship between fish oil intake and reduction in Raynaud's Syndrome, by noting that the literature concerning Raynaud's syndrome (shown in pink on the right) reports an increase in blood viscosity, while the literature about fish oil (blue, left) reports reduction in blood viscosity. The gray area in the middle indicates the common concept, blood viscosity, which establishes the connection between the other two terms.

corroborated this link (DiGiacomo *et al.*, 1989). The framework has been implemented in Swanson's Arrowsmith discovery system (Swanson *et al.*, 2001), and further extended by others in later years toward literature-based knowledge discovery (Lee *et al.*, 2007; Srinivasan, 2004; Srinivasan and Libbus, 2004).

Another way of uncovering new knowledge is by treating text as raw data, while searching for common motifs and patterns within it (Shatkay *et al.*, 2015; Shatkay *et al.*, 2000). This use of text is similar to the way in which homology and recurring motifs are scanned for on genomic and proteomic sequences, aiming to reveal relationships among such biological entities. Like genomic sequences, the text is viewed as a sequence of symbols, words, terms, phrases, or grammatical objects, and the statistical properties of their distribution across documents are used to expose similarities and connections among different text passages. Unlike most biological data, text components have readily understandable semantics, making results of such statistical pattern analysis easy to interpret and to validate. Early work establishing this direction included the utilization of statistical theme models in the gene-literature in order to identify functional relations among genes (Shatkay *et al.*, 2000). Similar ideas were employed for identifying sets of related genes or proteins by grouping together text passages discussing them (Chagoyen *et al.*, 2006; Renner and Aszodi, 2000).

A distinct but similar line of work directly employs text-based features associated with biological entities in order to predict biological properties such as protein homology, function, or subcellular location (Shatkay *et al.*, 2015; Chang *et al.*, 2001; Nair and Rost, 2002; Brady and Shatkay, 2008). Moreover, the integration of both text and sequence data into a unified prediction framework has shown very effective in improving prediction accuracy (Briesemeister *et al.*, 2009; Shatkay *et al.*, 2007). Thus, a direction that shows much promise in utilizing text is its integration as a source of data with other forms of biological data obtained from expression experiments, sequencing, or mutation analysis.

Another source of data that is currently being studied in conjunction with text is image information, where figures accompanying the text within medical records and publications are being examined as a source of additional knowledge (Ahmed *et al.*, 2010; Bockhorst *et al.*, 2012; Cohen *et al.*, 2003; Demner-Fushman *et al.*, 2012; Kalpathy-Cramer *et al.*, 2014; Ma *et al.*, 2015; Shatkay *et al.*, 2006; Xu *et al.*, 2008). This new direction that takes advantage of figures in addition to text holds much promise, both for supporting reliable curation of existing knowledge and for identifying significant pieces of information within the published literature.

Biographical Sketch

Hagit Shatkay is an Associate Professor and Director of the Computational Biomedicine and Machine Learning Lab at the Department of Computer and Information Sciences, University of Delaware. She has a PhD in Computer Science from Brown University, and an MSc and BSc in Computer Science from the Hebrew University of Jerusalem. Her research is focused on the development and use of machine learning and data-mining methods for addressing data-intensive problems in biology and medicine. She is an active member of the biomedical informatics and bio-text research communities, has presented many invited talks and international tutorials, and has authored, with Mark Craven, the book *Mining the Biomedical Literature* (MIT Press, 2012). Among many organizational and editorial roles, she is Section Editor for Knowledge Based Analysis at BMC Bioinformatics, associate editor in several journals, a board member of the International Society for Computational Biology (ISCB), has been an Area Chair of the Text Mining area at the International Conference on Intelligent Systems for Molecular Biology (ISMB) since 2008, co-organizer of the BioLINK Special Interest Group on linking biology and literature at ISMB, on the advisory board of BioASQ since its inception (2012), the steering committee of for TREC-Genomics 2005–2008, and others.

Biodiversity Databases and Tools

Background

Biological database is a large, organized library of life sciences information, collected from scientific experiments, published literature, high-throughput experiment technology, and computational analyses. It is associated with the usage of computerized software to store, update, query, and retrieve information within the system ([Kumar, 2005](#)). Database provides a convenient method to store enormous amount of data and allows biologists or researchers to collect the data, organize them systematically, analyze the data, and share the information with other researchers efficiently.

Biological data is often comprised of complicated data. There are different types of biological data, such as DNA sequence, protein sequence, protein structure, biodiversity, and many other specialized fields. Development of a database should acknowledge the complexity of the database content the capability of the technology in managing the complex data. In this article, we focus on biodiversity databases and tools, focusing on important projects done in this field. We also discuss the importance of biodiversity databases and the future direction anticipated inline with the advancement of technology and ICT.

Biodiversity Databases

Recent developments in information and communication technology have given birth to new experiences in the integration, analysis and visualization of biodiversity information, leading to the development of biodiversity databases ([Canhos *et al.*, 2004](#)). It includes application of information technology to the management, algorithmic exploration, analysis and interpretation of primary data regarding life, particularly at the species level of organization ([Soberon and Peterson, 2004](#)).

Biodiversity databases deals with managing information of unnamed taxa that are produced by environmental samples or sequencing of samples, and also cover the computational problems specific to the names of biological entities. Algorithms are developed to cope with those problems. For example, [Ch'ng \(2009\)](#) developed a segmentation algorithm for entity interaction, which increases the efficiency of real-time simulation that models the biotic interactions of large population datasets. Besides, biodiversity databases involve development of the syntax and semantics for publishing and integrating biodiversity information, while Darwin Core archive is the data standard developed to improve interoperability ([Wieczorek *et al.*, 2012](#)).

Existing Biodiversity Databases

Antweb

[AntWeb \(2018\)](#) focuses on ants, and it features as an image database. Being the leading online database of specimen records, images, and natural history information on ants, it aims to publish to the scientific community the high-quality images of global ant species. AntWeb focuses on data at specimen level and the corresponding images of the specimens. besides distribution maps. It accepts contributions on natural history information and field images that are linked directly to taxonomic names. Its content are also provided to the Global Biodiversity Information Facility ([gbif.org](#)), the Encyclopedia of Life ([EOL.org](#)) and Wikipedia (see "Relevant Websites section").

Fishbase

Fishbase (see "Relevant Websites section") ([FishBase.org, 2017](#)) is a global text and image database on finfishes. It contains a wide range of data on all species currently known worldwide. This includes information on the taxonomy, biology, trophic ecology, life history, uses, and historical data reaching back to 250 years. The detailed information in the database, which includes online analytical and graphical tools, cater to the needs of stakeholders, consists of researchers, scientists, policy makers, fisheries managers, donor, conservationists, teachers, and students. FishBase aims to provide for sustainable fisheries management, biodiversity conservation, and environmental protection.

Georgian Biodiversity Database

The Georgian Biodiversity Database (see "Relevant Websites section") ([Georgian Biodiversity Database, 2015](#)) focuses on the biological diversity of Georgia, and to a certain extent, the Caucasus ecoregion. This database can be categorized as a text and

image database, but mostly as an image database. This resource aims to introduce its biological diversity to the worldwide scientific community and also to any users alike. The Georgian Biodiversity database contains species list from terrestrial and freshwater ecosystems of Georgia, categorized according to the taxonomic hierarchical system. It also contains brief information on the individual species and higher-order taxa, including verbal descriptions of key ecological features and range, systematic remarks, bibliographies, images, and distribution maps.

Species + Database

Species + (see “Relevant Websites section”) ([Species +, 2017](#)) is a text database developed by UN Environment World Conservation Monitoring Centre (See Relevant Websites section) and the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES) Secretariat ([cites.org](#)). It is designed as a centralized data warehouse for accessing key information on species such as Legal, Names, Distribution, References, Documents, and many others.

Freshwater Ecoregions of the World, FEOW

The main focus of this database is Freshwater biodiversity and it is known as a text and image database. FEOW (see “Relevant Websites section”) ([FEOW.org, 2015](#)) provides a new global biogeographic regionalization of this planet’s freshwater biodiversity. It covers virtually all freshwater habitats on Earth, and is the first-ever ecoregion map. Together with associated species data, it is a useful tool for underpinning global and regional conservation planning efforts, particularly to identify outstanding and imperiled freshwater systems. It also serves as a logical framework for a large-scale conservation strategies, and a global-scale knowledge base for increasing freshwater biogeographic literacy.

Bacterial Diversity Metadatabase, Bacdive

The Bacterial Diversity Metadatabase is a Metadatabase that provides strain-linked information about bacterial and archaeal biodiversity. It features a text database. BacDive (see “Relevant Websites section”) ([BacDive, 2017](#)) represents a collection of organism-linked information covering the multifarious aspects of bacterial and archaeal biodiversity. Its content covers on taxonomy, morphology, physiology, sampling and environmental conditions, and molecular biology too. BacDive allows simple search at the portal entrance for a quick access to strain related information. As for TAXplorer, it can be used to select a strain by browsing through taxonomy.

Scalenet

ScaleNet (see “Relevant Websites section”) ([ScaleNet, 2016](#)) is a text database on scale insects (superfamily Coccoidea). It contains information about scale insects, their taxonomic diversity, summary of nomenclatural history, geographic distribution, ecological associations, and economic importance and a complete bibliography. To date it contains data from 23,708 references pertaining to 8187 valid species names.

Naturdata

Naturdata (see “Relevant Websites section”) ([Naturdata.com, 2017](#)) is a text and image database on Portuguese taxa. It contains checklist of Portuguese species with a page for each species pertaining to the taxonomy, synonyms, vernacular names, images, videos and distribution of the species. Until 2009, it was not possible to know the count and the type of species existed in Portugal. Some groups, such as the chordates, insects, arachnids were well inventoried, but in all, these groups represented a minimal percentage of Portugal’s biodiversity (with current information, about 5%). Beyond 2009, Naturdata was created as a data warehouse to collect, process and share information on Portugal’s biodiversity.

Pan-European Species-Directories Infrastructure, PESI

The Pan-European Species-directories Infrastructure, PESI (see “Relevant Websites section”) ([PESI, 2017](#)) features European taxa and functions as a text and image database. PESI is an authoritative taxonomic checklist of European species, including higher taxonomy, synonyms, vernacular names, and European distribution. It is Europe’s e-infrastructure for taxonomic information on species occurring in Europe. The data warehouse contains nearly 450,000 scientific names, 240,000 valid (sub) species names, and 140,000 vernacular names in 89 languages. Besides taxonomic information, PESI gathers relevant information on species, such as images, literature, distributions, and conservation status. PESI also offers its services to those who are interested to build their proprietary species applications.

Wikispecies

WikiSpecies (see “Relevant Websites section”) ([WikiSpecies, 2017](#)) focuses on all forms of life. This database is both a text and image database, with a free species directory on Animalia, Plantae, Fungi, Bacteria, Archaea, Protista, and all other forms of life. Currently, there are about 549,468 articles in the database. Interestingly, it is able to do taxon navigation, and includes higher taxonomy, synonyms, vernacular names, and references.

All Catfish Species Inventory, ACSI

All Catfish Species Inventory (see “Relevant Websites section”) ([ACSI, 2017](#)) is a text and image database on catfish, categorized by the genera. This inventory also estimates the total species count, aids in the discovery, description and dissemination of knowledge of all catfish species by the world consortium of taxonomists and systematists. The aim of ACSI is to discover around 1750 new species of catfish and describe between 2300 and 4600 new species of freshwater fishes, which will then result to a complete taxonomy of Siluriformes and later in the completed taxonomy of Otophysi, the clade containing over two-thirds of all freshwater fishes. Besides a completed taxonomy of catfishes with up-to-date identification guides, ACSI will include atlases, catalogues and checklists of species, phylogenetic studies of higher-level relationships among catfishes, and data analytics. It is expected to produce large samples of freshwater fishes from poorly collected regions to be added to permanent collections in US and foreign institutions, and enhanced international communication among fish taxonomists. The ACSI is expected to serve as a channel of communication among global taxonomists on topics pertaining to research, educational and outreach opportunities.

Arctos

Arctos (see “Relevant Websites section”) ([Arctos, 2017](#)) is a text and image database that features specimen holdings of several natural history museums, agencies, and accessible private collections. It consists of vertebrates, invertebrates, parasites, vascular and non-vascular plants, many with images and extensive usage data. It is both a community and a collection management information system. It provides fundamental research infrastructure for biodiversity data, and is intended for curators, collection managers, investigators, educators, and anyone interested in natural and cultural history. Besides serving individuals, Arctos is a consortium of museums that collaborate to serve data on over 3 million records from natural and cultural history collections. It is a collaborative effort to share data vocabulary and standards while curating and improving the quality of shared data such as agents and taxonomy. Arctos on its own is an information system that integrates data from a myriad of disciplines which are anthropology, botany, entomology, ethnology, herpetology, ichthyology, mammalogy, ornithology, paleontology, and parasitology. The content of Arctos includes specimen records, observations, tissues, endoparasites and ectoparasites, stomach contents, field notes and other documents, and media such as images, audio recordings, and video. Arctos displays all that is known about a museum record, and provides solutions to managing and integrating collections data with object tracking (barcodes, RFID tags), transactions (loans, borrows, accessions, permits), geospatial information (collecting events, coordinates), agents (people, organizations), and usage (publications, projects, citations).

ACB Database

The ASEAN Centre for Biodiversity (see “Relevant Websites section”) ([ACB, 2015](#)), is a text and image database consisting of information on amphibians, birds, butterflies, dragonflies, edible plants, freshwater fishes, mammals, plants, reptiles and Malesian mosses of Southeast Asia. Established in 2005, besides serving as a data store, ACB facilitates cooperation and coordination among the ten ASEAN Member States (AMS) on the conservation and sustainable use of biological diversity, and the fair and equitable sharing of benefits arising from the use of such natural treasures. ACB implements its programs and projects through five components, which are Programme Development and Implementation, Capacity Building, Biodiversity Information Management, Communication and Public Affairs, and Organizational Management and Resource Mobilization.

Vertnet

While most biodiversity databases are built as data warehouses, VertNet (see “Relevant Websites section”) ([VertNet.org, 2016](#)) uses the distributed database concept. It contains text and image specimens on vertebrates. VertNet is built upon conventional VertNET networks such as FishNet, MaNIS, HerpNET, ORNIS by combining them into a single interface for the community to discover, capture, and publish biodiversity data online. It is also an engine for training current and future professionals to use and build upon best practices in data quality, curation, research, and data publishing in taxonomy.

Database of Plant Biodiversity of West Bengal, WBPBDIVDB

The Database of Plant Biodiversity of West Bengal (see “Relevant Websites section”) ([WBPBDIVDB, 2017](#)) is a plant biodiversity database of West Bengal, and it functions as a text and image database. The database covers the richness of floral diversity of West Bengal from Terai, Duars, Darjeeling, the eastern Himalayan region and in the mangrove forests of Sundarbans. West Bengal is an important

biodiversity spot in India as it contributes around 12% of the total angiosperm diversity found all over India while the southern deltaic parts of West Bengal owns more than 60 species of the Sundarban Mangrove ecosystem, which outnumbers the total mangrove diversity in India. There are also information on the IUCN status of Plants in West Bengal, showing Family, RDB status, distribution sites and average altitudes. The Genera included are algae, bryophyte, dicotyledon, fungi, gymnosperm, lichen, monocotyledon and pteridophyta. It also shows the species and ecological statistics, by displaying total species and frequency of occurrences.

Reptiles Database

The Reptiles Database (see “Relevant Websites section”) ([The Reptiles Database, 2017](#)) is a text and image database on reptiles, containing taxonomic information, names, and photos on about 10,000 species and 2800 subspecies. This database provides a catalogue of all living reptile species and their classification. It covers all living snakes, lizards, turtles, amphisbaenians, tuataras, and crocodiles, emphasizing on taxonomic data, particularly names and synonyms, distribution and type data, and literature references. It has no commercial interest and therefore depends on contributions from volunteers. Most of the data comes from published sources, which are curated by editors.

iNaturalist

iNaturalist (see “Relevant Websites section”) ([iNaturalist.org, 2017](#)) is an online social network of nature enthusiasts sharing biodiversity knowledge. In 2014, the California Academy of Sciences acquired iNaturalist, and now serves as the home for this endeavor. iNaturalist records a life based on number of observations by the community, which is then noted by scientists and land managers, hence serves as a crowdsourced species identification system and an organism occurrence recording tool. The community in iNaturalist records observations, get help with identifications, collaborate with others to collect similar information for a common purpose, or access the observational data collected by other iNaturalist users. It is a unique database as the scientifically valuable biodiversity data is generated by the user’s personal encounters and experiences. Scientists and taxonomic experts can provide enormous value to the community by helping to identify observations.

Integrated Biodiversity Information System, IBIS

The Integrated Biodiversity Information System (see “Relevant Websites section”) ([IBIS, 2011](#)) is a text and image database focusing on Australian plants. It provides taxonomic information, collection details and photographs, incorporating the integration, retrieval and dissemination of biodiversity information via collections management of nomenclatural and taxonomic indices, information delivery, web services and federated database support. IBIS links the data held in the various collections of the Australian National Botanic Gardens, the Australian National Herbarium, the Australian Plant Image Index and the Australian Plant Name Index. IBIS is built upon open source solutions such as Apache, Perl and Java using the Oracle RDBMS for the application and SQL engine. The content uses global naming conventions such as HISPID, TDWG, and BioCase for information management and delivery.

Natureserve Explorer

NatureServe (see “Relevant Websites section”) ([NatureServe Explorer, 2017](#)) is a database that houses about 70,000 plants, animals, and ecosystems of the United States and Canada, with an in-depth coverage for rare and endangered species. NatureServe easily locates information on scientific and common names, conservation status, distribution maps and images for thousands of species, life histories and conservation needs.

Virtual Tour Database System of Rimba Ilmu Botanic Garden, University of Malaya

This system is a virtual reality (VR) application on plants in Rimba Ilmu Botanical Garden, University of Malaya (UM) (see “Relevant Websites section”) ([Rimba Ilmu Botanic Garden, 2016](#)), Kuala Lumpur, Malaysia. In this application, the VR technology was used to develop an innovative VR database system which includes visual analytics features. The interactive virtual tour functions side by side the biodiversity database, as it involves an online interactive website to be developed so that users have a virtual tour of a botanic garden and are able to select distinct hotspots throughout the garden. A biodiversity database that consists of the plant species details and information is linked to this interactive portal. The information on the plant species of Rimba Ilmu Botanic Garden such as taxonomy and locality, are stored in a plant database. Geographical representation data are also available in the portal. Visualizing multiple hotspots in a botanical garden using the concept of virtual tour is a novel method of visualizing biodiversity. There are seven hotspots which were selected according to significant plants within the hotspot. Overall, it is a portal on Rimba Ilmu that links to a plant species database and the virtual tours around the botanic garden. The application is a useful tool for biodiversity researchers, non-specialists and also for educating and engaging the public. This system is based on the effort started by [Sarinder et al. \(2007\)](#) in digitizing the local biodiversity using diverse computational tools and technology including building ontologies in biodiversity.

Fig. 2 Occurrences information in GBIF. *Source:* GBIF.org, 2017. GBIF. Available from: <http://gbif.org> (27.02.18).

The figure displays two side-by-side screenshots of the GBIF Occurrences search interface. Both screenshots show a green header bar with a leaf icon and navigation links: 'Get data', 'Share', 'Tools', and 'Inside'. Below the header, a green bar contains the word 'Occurrences' and a trash icon. A search bar with the placeholder 'Search all fields' and a magnifying glass icon is present. Below the search bar, there are two tabs: 'Simple' and 'Advanced'. The left screenshot shows the 'Simple' search mode, and the right screenshot shows the 'Advanced' search mode. Both modes display a list of 20 searchable fields, each with a dropdown arrow. The fields are: Record License, Scientific Name, Basis Of Record, Location, Year, Month, Dataset, Country Or Area, Issue, Media Type, Publisher, Institution Code, Collection Code, Catalogue Number, Type Status, Recorded By, Catalogue Number, Type Status, Recorded By, Record Number, Occurrence ID, Organism ID, Publishing Country Or Area, Elevation, Depth, Locality, Water Body, State Province, Repatriated Data, Protocol, Last Interpreted, Event Date, and Establishment Means.

The next section presents two very important and large biodiversity databases and tools widely used by scientists; the Global Biodiversity Information Facility (GBIF) and the Encyclopedia of Life (EoL) database. These databases are discussed as case studies in the next section.

Case Studies on Biodiversity Databases

This case study describes two databases, GBIF database and EOL database, which are some of the best examples of existing biodiversity databases and tools that are available on the web. It gives a description of the research and biodiversity needs motivated by a set of technologies with front end portals providing internal and external users with a comprehensive list of capabilities.

GBIF: Free and Open Access to Biodiversity Data

The Global Biodiversity Information Facility, GBIF (see "Relevant Websites section") (GBIF.org, 2017) is an open-data research infrastructure which is funded by governments around the globe, facilitating access more to over 377 million records from more than 400 data publishers (Ariño, 2010). GBIF arose from a 1999 recommendation by the Biodiversity Informatics Subgroup of the Organization for Economic Cooperation and Development's Megascience Forum. One of its report concluded that "An international mechanism is needed to make biodiversity data and information accessible worldwide", stressing the fact that this mechanism could produce many economic and social benefits and enable sustainable development by providing sound scientific

evidence. Following this mechanism, in 2001, GBIF was officially established through Memorandum of Understanding between participating governments.

The aim of GBIF is to provide easy access to text and image data on all types of life on Earth. The coordinator with its network of participating countries and organizations provide data owners around the globe with common standards and open-source tools that allows sharing of information such as the location and date of the recorded species. GBIF data is derived from multiple sources, including from museum specimens collected in the past and geotagged smartphone photos shared by amateur naturalists in recent dates (Fig. 1).

The GBIF network draws all the sources together using the Darwin Core standard, which forms the basis of millions of species occurrence records. An assessment of data count resulted in 267 million occurrences records (Fig. 2) accessible through the GBIF network in which 62% belonged to Kingdom Animalia, followed by Kingdom Plantae (23%), Fungi (1.55%), Protozoa (0.67%), and Bacteria (0.59%) (Gaiji *et al.*, 2003). Every year, hundreds of peer-reviewed publications and policy papers are written based on datasets published by GBIF, covering topics from the impacts of climate change and the spread of pests, to priorities for conservation and protected areas, food security and human health (see “Relevant Websites section”).

The role of GBIF is to provide a discovery window on the posted statistics. Such a position requires reconciling, decoding and publishing the crucial key attributes: taxonomic, temporal and geospatial (Gaiji *et al.*, 2003). The searchable fields in GBIF is presented in Fig. 3 while an example of species page is presented in Fig. 4. Fig. 5 shows example of georeferenced records.

GBIF's ultimate plan is to serve the needs of GBIF's global community and infrastructure to the next decade by empowering global network, enhancing biodiversity information infrastructure, filling data gaps, improving data quality, and also by delivering relevant data.

EOL: Free, Online Collaborative Encyclopedia

The Encyclopedia of Life (EOL) (see “Relevant Websites section”) (EOL.org, 2017) is a free, online collaborative encyclopedia intended to document all of the 1.9 million living species known to science (Fig. 1). It gives global access to knowledge about life on Earth (Fig. 6).

Under the umbrella of EOL, data previously scattered in books, journals, databases, websites, specimen collections, reports are now collated and made available to the public, in the form of articles, media, maps, data in a single website with a collection of application programming interfaces (APIs) (see “Relevant Websites section”). An example of a species page is shown in Fig. 7

The screenshot displays the GBIF species page for *Andrographis elongata* T. Anderson. The page is structured with a green header containing navigation links (Get data, Share, Tools, Inside GBIF) and a search bar. The main content area is divided into several sections:

- Classification:** A sidebar on the left lists the taxonomic hierarchy: Kingdom: Plantae, Phylum: Tracheophyta, Class: Magnoliopsida, Order: Lamiales, Family: Acanthaceae, and Genus: *Andrographis* Wall. ex Nees.
- Species:** The species name *Andrographis elongata* T. Anderson is displayed, followed by a list of synonyms: *Cryptophragmium cordifolium* Nees, *Cryptophragmium elongatum* Nees, *Justicia clandestina* Russell, *Justicia clandestina* Russell ex Wall., *Justicia cordifolia* B. Heyne, *Justicia cordifolia* B. Heyne ex Wall., and *Justicia elongata* Vahl.
- Species Page Header:** The species name *Andrographis elongata* T. Anderson is prominently displayed, along with its publication information: "Published in: Anderson T (1867) An Enumeration of the Indian Species of Acanthaceae. (continued.). Journal of the Linnean Society of London, Botany 9(40): 455-526. doi: 10.1111/j.1095-8339.1867.tb01309.x. Source: Catalogue of Life".
- Overview and Occurrences:** The page includes tabs for "OVERVIEW" and "REFERENCE TAXON". A green button indicates "94 OCCURRENCES". Below this, a section titled "15 OCCURRENCE RECORDS WITH IMAGES" shows a grid of specimen images.
- Georeferenced Records:** A map section titled "6 GEOREFERENCED RECORDS" shows a world map with yellow dots indicating the locations of the records, primarily in South America and Africa.

Fig. 4 Example of species page in GBIF. Source: GBIF.org, 2017. GBIF. Available from: <http://gbif.org> (7.02.18).

Fig. 5 GBIF's georeferenced records. *Source:* GBIF.org, 2017. GBIF. Available from: <http://gbif.org> (27.02.18).

while **Fig. 8** shows an example of textual and image content in the EOL website (see "Relevant Websites section"). The type of taxonomy content is shown in **Fig. 9**.

EOL is supported by some very important institutions, which are Atlas of Living Australia, La Comisión Nacional para el Conocimiento y Uso de la Biodiversidad (CONABIO), Harvard University, Marine Biological Laboratory, New Library of Alexandria, and also Smithsonian Institution's National Museum of Natural History. In addition, EOL collaborates with global bioinformatics projects, like the Biodiversity Heritage Library (BHL), Barcode of Life (BOLD), Catalogue of Life (COL), and Global Biodiversity Information Facility (GBIF) (see "Relevant Websites section").

Essentially, the Encyclopedia of Life serves the global community and by collaborating with its Global Partners, EOL seeks to remove the barriers of geography and language to support international professional and citizen scientists interested in biodiversity and related topics (see "Relevant Websites section"). More than just a database, EOL offers tools and resources that help users harness and apply the information found on EOL.

EOL's mission is to increase awareness and understanding of living nature through a service engine that gathers, generates, and shares knowledge in an open, freely accessible and trusted digital resource (see "Relevant Websites section"). EOL has achieved its mission as it is currently one of the biggest and widely accessible data store on biodiversity. Over time, the content in EOL will be richer as more partners joins this initiative and the current partners stay active in depositing data into the portal.

Importance of Digitizing Biodiversity Information

The collection of biodiversity information plays a critical role in understanding biodiversity and ecosystem. The significance of biodiversity databases are highlighted in this section.

Fig. 6 EOL website. Source: EOL.org, 2017. Encyclopedia of Life Home Page. Available from: <http://www.eol.org> (27.02.18).

Biodiversity and Environmental Change

Biodiversity databases and tools allows documentation of the biological diversity of life and demonstration of changes in the environment that have taken place through time (Baird, 2010). The presence or absence of a species as well as their frequency changes in a geographic region over the course of time are documented by examining the records. If a gradual decline of an important species is observed, it may serve as an indicator whether a recovery program should be carried out to restore the population of the species. The collections that are well documented and deposited can offer proof that the program was successful, provide evidence that changes has taken place, and can help to effectively monitor rare, threatened and endangered species.

Invasive Alien Species and Biosecurity

Other than monitoring endangering species, biodiversity informatics is capable of revealing the invasive alien species that are threat for biodiversity. Increasing travel, trade, and tourism associated with globalization and expansion of the human population have facilitated intentional and unintentional movement of species beyond natural biogeographical barriers (Forest Research Institute Malaysia, 2011). These species are known as alien species and many of them have become invasive. Invasive alien species are known to cause biodiversity loss and lead to a nation's economic loss. Thus, it is critical to differentiate native from alien species, and respond rapidly to these threat, either to remove the species from a region, or suppress their population growth if unable to remove it.

Besides revealing invasive alien species, biodiversity informatics allows prediction of potential of a non-native species to be invasive alien species. Faulkner *et al.* (2014) has created and applied a simple, rapid methodology for developing invasive species watch lists. The watch lists are created using three predictors of three invasion success: History of invasion, environmental suitability and propagule pressure. The authors claim that building the list may be an important step in developing biosecurity scheme, especially for resource poor regions.

Public Health and Wildlife Disease

There are many infections that manifest themselves in human and non-human populations, such as H1N1 Influenza, West Nile Virus, Lyme disease, tuberculosis, Ebola Virus, and SARS. For these and other zoonoses, approximately 70% of new important disease affecting human health are believed to have a wild animal source, and can have profound impacts on human health and economy (Blancou *et al.*, 2005).

Using the occurrence data from GBIF, [Pigott et al. \(2014\)](#) mapped the area potentially at risk from outbreaks of Ebola virus, based on the environmental niche of bat species believed to act as reservoir hosts of the disease. The authors determined the national population at risk, and claimed that this would be a strong rationale for improving, prioritizing, and stratifying surveillance for EVD outbreaks and diagnostic capacity in these countries.

Economics and Regulatory Framework

The Economics of Ecosystems and Biodiversity (TEEB) (see "Relevant Websites section") is a global initiative focused on "making nature's values visible". The objective of TEEB is to introduce the importance of putting economic value to biodiversity, particularly for policies and decision making at all levels. It follows a structured approach to valuation of ecosystem in economic terms in order to recognize the benefits of biodiversity protection, which is inline with the objectives of the Convention of Biological Diversity. While economic impact studies on biodiversity is still new, sooner or later it is going to change the way humans perceive biodiversity.

Access and Benefit Sharing

The obvious significance of digitization of biodiversity information is dissemination of information globally online. Before digitization, the information is held by institutes in developed countries, whereas scientists may do their field work at

[learn more about this article](#)

With the exception of Antarctica, Australia, New Zealand, Madagascar, Japan, and most oceanic islands, native populations of cats are found worldwide, and one species, domestic cats, have been introduced nearly everywhere humans currently exist. Although some authorities recognize only a few genera, most accounts of Felidae recognize 18 genera and 36 species. With the exception of the largest cats, most are adept climbers, and many are skilled swimmers. Most felids are solitary. Often, felids are separated into two distinct subgroups, large cats and small cats. Generally, small cats are those that, due to a hardening of the hyoid bone, have an inability to roar. Felidae consists of 2 subfamilies, Pantherinae (e.g., lions and tigers) and Felinae (e.g., bobcats, pumas, and cheetahs).

Felids are perhaps the most morphologically specialized hunters of all carnivores, often taking prey as

underdeveloped country. Digitization allows researcher to access to the information remotely via the web. Besides, digitization allows sharing of information among researchers. The information may be integrated and analyzed to contribute to their study.

Future Directions and Closing Remarks

The production of biodiversity data has accelerated enormously in the past few years, and this has led to the creation of databases and tools to seek deeper understanding of the myriad of values it offers. While every biodiversity and conservation entity in the world is trying to collate and store their data in a digital form, without sharing it in a central repository, the actual value cannot be perceived. The engagement programs started by world class organizations like GBIF and EOL have introduced novel methodologies in managing, accessing and visualizing primary and secondary biodiversity datasets. It is hoped that, with the integration of biodiversity data globally, new discoveries in science is produced, besides creating a new economy in this field.

Apart from curated databases, we strongly belief that species identification, which is currently dependent on expertise of a few individuals, can be automated using technologies in pattern recognition and semantics, for both image and text retrieval. Future efforts in biodiversity should focus on areas such as (1) to what extent can biodiversity be linked using the current technology; (2) how does biodiversity fits into Big Data Analytics; and (3) to what extent automated systems can help in returning accurate species identifications with annotations? With these findings, we should aim to build integrated biodiversity platforms, focusing on semantic search and big data analytics, along with high throughput automated systems capable of accurate species identifications in seconds. This potential system can then be used as a benchmark for indexing millions of identified species.

The actual value of a species can only be known if sufficient data about the species is linked, in a manner when new insights can be discovered easily, through the technology of linked data. This is similar to the social media data linking people such as Facebook, Twitter, LinkedIn, ResearchGate, ResearcherID, WeChat and Hangouts. A similar idea could be implemented for specimens or species.

Technology such as semantic web and ontologies, big data analytics, cloud computing and data science are controlling the ICT age and many new discoveries are anticipated. We strongly believe application of these technologies in biodiversity studies will help scientists in future investigation, inquiry, reasoning and analysis of biodiversity data. Moreover, students, policymakers and stakeholders will gain insight to biodiversity data captured and interpreted precisely.

Challenges in Creating Online Biodiversity Repositories With Taxonomic Classification

Mohd NM Ali, Amy Y Then Hui, and Sarinder K Dhillon, University of Malaya, Kuala Lumpur, Malaysia

© 2019 Elsevier Inc. All rights reserved.

Introduction

Presently many biodiversity databases with species information annotations are available online. Although these databases tend to focus on specific taxa, accurate and updated taxonomic classification remain challenging given that new species are being discovered from time to time while extant species may become or have gone extinct. According to the United Nations Environment Programme, scientists estimate that 150–200 species of plants, insects, birds, and mammals become extinct every 24 h and there are around 15% of mammal species and 11% of bird species that are classified as threatened with extinction (Vidal, 2010). On the other hand, new species are being described every three days over last decade (Tobias, 2010). This situation depicts the challenges taxonomists and biologists have to face in order to keep up with updated, accurate information on biodiversity profiles and classification. Most of the online taxonomic databases or portals contain information on authoritative source(s), namely who is managing the data, how it is curated and credibility of the data. Most of these authoritative sources are fellow scientists or researchers, who form a group that manages the taxonomic information shared to the public.

Taxonomy is a field of classifying living things through defining and naming based on shared characteristics. Over time, there are varying definitions of taxonomy within the scientific community, but the core of its practice is revolved around the conception, naming, and classification of groups of organisms. The Linnaean Taxonomy, a system for categorizing organisms and naming living things through a binomial nomenclature, is regarded as the origin of the practice. This system is named after Carl Linnaeus, a Swedish botanist and the father of taxonomy, who introduced the science of naming organisms (either living or extinct) through the usage of two descriptors, namely the genus that the organism belong to, followed by the species modifier. For example, a Chinook salmon or better known as king salmon, has the scientific name of *Oncorhynchus tshawytscha* where *Oncorhynchus* is the genus and *tshawytscha* is the species modifier.

In modern biological classification, taxonomic hierarchy is used to place organisms in increasingly exclusive groupings or ranks, starting with the broadest rank of domain, followed by kingdom, phylum, class, order, family, genus, and species. Within these categorizations, there are more specific groups for them known as subdivisions, which further clarify their classification ranks. For example, superclass, subclass, infraclass, or parvclass form taxonomic subdivisions of the class rank.

Taxonomic classification is one of the main branches of biology, practiced by experts known as taxonomists. The roles of trained taxonomists are clear, which include describing new species and conducting taxonomic revisions to described species as needed. Such exercises are not easy as prior knowledge of the taxa of interest is required and formal taxonomic training on the subject of study is crucial. Incorrect identification of biological entities will introduce misleading information and errors in subsequent work pertaining to that particular information, e.g., worldwide distribution of a species. As such, competent taxonomic work is fundamentally important for the understanding of biology and conservation of biodiversity.

Taxonomy is separated into several sub-branches, each with their unique approach of classifying organisms. Some of the popular sub-branches are alpha taxonomy, beta taxonomy, cytotaxonomy, chemotaxonomy, and cladistics taxonomy. Alpha taxonomy and beta taxonomy both deal with external morphology; however the latter includes internal features such as anatomical characteristics and organ studies. Cytotaxonomy deals with plant classification through the use of cytology (cell) studies, which greatly aid plant classification. Chemotaxonomy also focuses on plants, but utilizes information on chemical constituents of the plants for classification. A widely used taxonomic approach in the modern age is the cladistic taxonomy which groups organisms into clades based on shared, derived characteristics from the most recent common ancestor.

Taxonomy Related Issues

It is evident that even in the age of technology, where information can be accessed and shared anywhere in the world via the internet, dedicated online databases have proven to be useful for the scientific community to publish their findings. The use of an online database is a necessity for taxonomic research; however there are a number of issues related to biodiversity conservation and data management which will be discussed. The first issue, which is quite alarming, is insufficiency of taxonomists or taxonomic research capacity. This is essentially a global issue affecting biology in general. A study showed that although systematic research as a whole has been on the increase, traditional taxonomists, a unique breed of scientists with specific skill sets that are difficult to train and replace, are dwindling in numbers (Lee and Palci, 2015). Another study on the other hand showed that the number of taxonomists has actually been increasing; however the number of species described per taxonomist has not seen decline for poorly studied taxa such as beetles and parasitic wasps (Bacher, 2012). This suggests that much remains to be done for new species discovery and description. One recent study pointed out that while taxonomy is still very much alive, taxonomists are struggling to obtain sufficient funding and appropriate recognition for their field (Bik, 2017).

The second issue, which is linked to the previous, is about species unknown to science going extinct before they are discovered and described. It is commonly accepted in the scientific community that at the current rate of extinction, many species will die before they are managed to be described by science (Dirzo and Raven, 2003; Gaston and May, 1992). In a research done in the Cape Floristic Region (one of the smallest and popular biodiversity hotspots in South Africa), it was reported that there is a finite number of species that may be processed and identified by a taxonomist during his/her working life (Treurnicht *et al.*, 2017). The same research further claimed that the current state of technology and infrastructure does not support an increase in individual taxonomic output; improper operational concepts practiced by taxonomists may also affect a taxonomist's output.

The third issue is regarding the correct identification of species by biologists in general and by taxonomists, which is fundamental for any taxonomy-based studies. The field of taxonomy is thwarted by inconsistent taxonomy literature and vague species descriptions containing incorrect identifications due to work by amateur taxonomists, or inadequate access to original works on the species. Also as mentioned earlier, there are various sub-branches of taxonomy. The use of integrated taxonomic methods, i.e., other branches in conjunction with traditional morphological methods, has led to taxonomic revisions for many known species; this indicates that accurate classification of species remains an issue. However, in modern taxonomy practice, traditional morphology tends to be overlooked in favor of genetic studies. Decoupling of traditional and modern taxonomy affects the type of data shared on online databases, which usually have groups or consortium of sorts regulating these information. Given the present age of Big Data, it is impossible to review and regulate all taxonomic information needed for correct species identification. This is an issue which both taxonomists and data scientists need to tackle in order to provide reliable data for and to facilitate accurate classification of living things.

Impact of the Issues to Online Taxonomy Databases

The issues raised above will create an impact on online taxonomy databases, particularly pertaining to users' expectation to have updated content available to them whenever needed. The decline in the number of expert taxonomists in the near future will impede progress in taxonomic research (Lim and Gibson, 2010). This situation is keenly felt in developing countries, which are often areas of high biodiversity and where not only the number of taxonomists is low but funding for basic taxonomic research is scarce; the net result is often inadequate data quality and analysis and poor data management.

Another impact is bias in research funding. Traditional taxonomy, a fundamental branch of biology, is not perceived as popular as molecular studies, the latter usually preferred by funding bodies. For any research community, funding availability is critical to the progress of the research. In this day and age, dissemination of updated information is done primarily via online means; insufficient funds will also impact dedicated curation of online taxonomic data. Creative funding opportunities must be sought to alleviate the biodiversity crisis, and to promote progress of research on of online taxonomy databases.

Benefits and Risks of Putting Data Online

The necessity for scientific research, taxonomy notwithstanding, to be merged with computational technology is evident (Bik, 2017); this includes making research information publicly available and updated. One benefit of having research data online is to increase visibility of the research, to make them accessible for research continuity and to avoid loss of invaluable data. Even though 'old data' might not have a direct or immediate value, such data might generate new findings after recalibration. Another benefit for putting research data online is to provide public documentation of a topic of research even though it has not gone through a peer-reviewed process. This minimizes the possibility of research hijacking or another party claiming authority over the same research topic as their own. Besides sharing research data online, it is possible to link the data to other information sources via data sharing portals. This enables new analysis and research while increasing the value of the previous research. Current online databases have already started this practice where taxonomic data are linked to genetic databases pertaining to a taxonomy rank. This is discussed further in the next section.

However, there are valid reasons why scientists may not prefer to share their data online. The human factor is perhaps the main stumbling block to online publishing. Publishing taxonomy data exposes information into the public domain. Unlike peer reviewed publications where researchers get scientific credit via the citation process (an important academic performance measure), taxonomists publishing raw data tend to remain anonymous while the web data curators governing the information are known. Another risk is plagiarism. Scientists fear sharing data openly, especially from research in the initial stages, as unethical researchers might illegally use these data and represent them as their original work. Data published online is prone to security threats. There is a risk of data being hacked and manipulated. Data owners who are not computationally savvy or bogged down by other research work may not be able to manage the online data content, which involves creating a change log, and notifying users about the change. Finally, there is a risk of inappropriate use of data whereby they are used to conduct inappropriate or unethical research.

Comparison Between Databases

Taxonomic classification data contain information on scientific names, taxon ranks, morphological features, distributions, and other related information; all these information provided in species profile databases, species lineage or classification information

are valuable. The lineage or classification data in most databases are usually linked to sequence data repositories, such as GenBank (see “Relevant Websites section”). Online taxonomic databases have clearly defined ways to manage taxonomic information. Here we discuss some of the popular databases, with emphasis on fish taxonomy.

FishBase (see “Relevant Websites section”) is a portal managed by the FishBase Consortium group and is one of the trusted online resources on fish. This portal holds a huge amount of information on fish but here we are concerned only with taxonomic classification. FishBase displays species classification data on individual species profile page, such as common names, climate, distribution, and size parameters; the portal presents relevant information specific to the species without covering the species lineage or phylogenetic tree. Nevertheless, FishBase provides a link to the Deep Fin Classification for every species stored in its database.

Another popular taxonomic database is the NCBI Taxonomy Browser managed by the NCBI group (see “Relevant Websites section”). It provides some of the most comprehensive information for a species. In addition to displaying a full lineage of any species of interest, it also provides links to its mitochondrial genetic code, nucleotide sequences and protein sequences. The coverage is elaborated with external information sources which include origin of the name, author, abbreviated taxonomy, and biotic interactions.

FishBase is a database made to handle solely fish data while the NCBI Taxon is developed for classification of living organisms. As such there is a difference in the way data are displayed and organized. FishBase displays information related to the fish species, leaving out information about the lineage of the species. NCBI Taxon, on the other hand may increase the coverage by elaborating on the genetic information of the classification for interested users; when any doubt arises, they may challenge the findings. The possibilities of using these data to produce new research avenues are endless and it is up to the scientific community on how to use it.

Next, we discuss how Wikipedia (see “Relevant Websites section”) handles species information and compare it to more credible sources such as FishBase and NCBI Taxon discussed above. Wikipedia, although not necessarily an authoritative source, is often a preferred choice among students or even researchers wanting to get a quick overview on any topic. Data in Wikipedia are generated mostly by voluntary contributors; thus, available taxonomic information provided on each species page may vary depending on the popularity and extent of knowledge of the species. Nevertheless, there are some standards set by Wikipedia for publishing species information such as full scientific names, scientific classification, conservation status, binomial name, synonyms (if available), and references used to write the species article. Information on species classification, however, is basic and linked to a Wikipedia article page, not another authoritative source. [Table 1](#) presents the comparison between popular online taxonomic databases, including those discussed above.

Ontology and Taxonomic Classification

With the birth of a new Web commonly referred to as the Semantic Web, it is imperative for scientists to embrace the world of data sharing and Big Data. This shift in scientific operation and paradigm requires that the wealth of scientific data, in all manners of format and complexity, be captured and mapped correctly especially in the context of species classification. A preferred way to do this for species data is in the form of an ontology, a formal naming convention that defines any domain of interest and handles information about the types, properties, and interrelationships of these entities.

Ontology is different from a database in terms of their data structure and the way to query data. The most important difference is the triple data structure of an ontology, which creates relationships between a class and properties. As such there are differences in the purpose of creating an online database versus an ontology. The latter is created primarily to give definition to a certain domain; an example is the Gene Ontology that is created specifically to describe genes. It is generally advisable to create lower level domain ontologies with a defined focus, such as gene sequences and skeletal structure, since it is easier to handle and limit the amount of information and to reuse it for other ontologies or databases. Creation of ontologies for large-scale domains such as human or flowers would result in huge amount of data that need to be managed which may contain information that are vague.

In 2017, we published a Fish Ontology (FISHO) (see “Relevant Websites section”), with the aim of performing automated identification of fish using taxonomy ([Ali et al., 2017](#)). The FISHO consists of 652 classes (terms), and 27 object properties (relationships) (can be viewed at “Relevant Websites section”). There are 10 main classes which act as the core classes covering fish-related and non-related terms within the FISHO structure. The FISHO provides terms related to fish and infers species related information based on data that are fed to the ontology. The current version of the FISHO is able to classify jawless fish, early jawed fish and living fossil fish. The FISHO contains 253 classes dedicated to fish studies and 38 classes related to fish sampling processes. [Table 2](#) shows the adoption of the terms in the FISHO using 3 sources which include an authoritative book on fish ([Helfman et al., 2009](#)), the Vertebrate Taxonomy Ontology ([Midford et al., 2013](#)), and the NCBI Taxon ([Federhen, 2016](#)) ([Fig. 1](#)).

The FISHO is created using Protégé ([Protégé, 2018](#)), an open source ontology editor provided by the Stanford Center for Biomedical Informatics Research at the Stanford University School of Medicine. This software contains all the tools needed to develop the FISHO with many supporting features that can assist in the development and visualization of ontology. One of the feature provided by Protégé is the inferring capabilities. In [Fig. 2](#), we show the results of the inferring process within the FISHO. Inferred results of a sample specimen with certain parameters are shown with bright orange color. Once it is inferred, more results can be gained from the inferred results; as an example, Specimen5 was recognized not only as a whale in Infer Result A, the FISHO also inferred that it is not a fish, but a mammal. For Sample2, it is recognized as a longtail carpet shark after the inferring process, and furthermore recognized as an early jawed fish in Infer Result B.

Table 1 Differences between online databases in handling and displaying taxonomic classification information

Database name	Purpose	Classification tree	Link to taxonomic information source	Related Data complementing the taxonomy data	External Links related to the taxonomy data
FishBase (www.fishbase.org)	Fish profile	Partial	Yes	Names, Synonyms, Climates, Size, Distribution	Minimal. (Catalog of Fishes, Deep Fin Classification)
NCBI taxon (www.ncbi.nlm.nih.gov/Taxonomy/taxonomyhome.html)	Taxonomy	Complete including ranks subdivisions	Yes	Taxon Id, Inherited Blast Name, Genetic Code, Mitochondrial Genetic Code, Entrez records	Moderate. (Encyclopedia of Life, Global Biotic Interaction, Dryad Digital Repositories, Arctos Specimen Database)
Wikipedia (www.wikipedia.org)	General knowledge	Partial	Yes	Description, History (if available), Elaborated Information (based on necessity and availability), conservation status, binomial name, synonym	Minimal. (IUCN Redlist, and random links, depending on the author)
WoRMS (www.marinespecies.org)	Marine species registry	Partial	Yes	Status, Ranks, Parents, Original name, Synonyms, Vernacular names, Environment, and Distribution	Comprehensive. (Barcode of Life, Biodiversity Heritage Library, Encyclopedia of Life, and Fishbase to name a few)
The IUCN red list of threatened species (www.iucnredlist.org)	Red list of threatened species	Full	Yes	Names, synonyms, assessment information, population, usage, threats level, and conservation actions	None.
Barcode of life data system (www.boldsystems.org)	Generation & application of DNA barcode data	Full	No	Sample ID, Museum ID, Collection data, Sequencing records (sequence ID, GenBank Accession, Genome, Locus, Nucleotides, Amino Acids, and Illustrative Barcode)	Minimal. (Genbank)

Table 2 Term adoption in the Fish Ontology

Example of terms	Sources			Implementations in the Fish Ontology
	Helfman (2009)	Vertebrate Taxonomy Ontology (VTO)	NCBI Taxon	
Furcacaudiformes (order)	Classified as Subclass of Thelodonti (superclass)	Classified as subclass of Agnatha (class)	Not classified	Follows and reuses the VTO terms
Jawless fish	Contains species and information for jawless fish species	No classes and annotations found, but related species are classified	No classes and annotations found, but related species are classified	Follows Helfman (2009) for labeling
Lobe finned fish	Classified as Actinopterygii (page 4)	No classes and annotations found, but related species are classified	Classified as Coelacanthiformes	Follow Helfman (2009) for classification and labeling
Gobiidae (family)	Listed and classified as family	Listed and classified as family	Listed and classified as family	Follows and reuses the VTO terms
Oxudercinae (subfamily)	Not listed or classified	Not listed or classified	Classified as a subclass of Gobiidae (family)	Follows and reuses the VTO classification up to the lowest existing taxonomic terms covered (Family Gobiidae). Adopts NCBI Taxon terms for subfamily Oxudercinae onwards

The FISHO was reviewed by several experts, one of them being a museum curator who raised concerns over taxonomic classification within the ontology. From a cladistics standpoint, mammals are derived from fish and the inclusion of mammals (and other tetrapods) under Sarcopterygii (an ancient fish group with lobed fins) allows it to be a monophyletic group. However, the main point of creating the ontology is not primarily for taxonomic classification, but to create an automated fish recognition using taxonomy. Presently in the FISHO, the class Mammalia is not placed within the general fish classification structure but under the Chordata phylum. Inclusion of the Mammalia class in the FISHO is due to the existence of some aquatic mammals, such as

Fig. 2 Inferring process in the FISHO.

whales and dolphins, which may be erroneously classified as fish. Under the ideal FISHO classification (in our opinion), whales would not be recognized as a fish but a mammal. As such, the consequence of explicitly classifying mammals under Sarcopterygii in the FISHO is such that a whale would then be recognized as both a mammal and a fish. Further explanation of this situation is shown in Fig. 3, where we show the specific use case of other sources compared to the FISHO.

Another comment from the reviewer highlighted the confusion about jawless fishes in the FISHO. From a phylogenetic point of view, Agnatha (jawless fish group that includes lampreys, hagfish and ostracoderms) is not a monophyletic group. However, our

Fig. 3 Different usage of other classification sources compared to the FISHO. The leftmost figure shows how the FISHO classify mammals compared to the NCBI Taxon and the Vertebrate Taxonomy Ontology (VTO).

purpose of including jawless fishes in the FISHO was to capture it as one type of fish grouping or characteristic. For example, a hagfish would be characterized as (or having the attribute of) a jawless fish in the FISHO. This grouping term is not intended as a form of taxonomic classification (i.e., this term is not a class under taxonomic rank, but under Fish Group in the FISHO). The nature of the ontology is such that broad inclusion of relevant fish-related terms such as 'jawless fish' would improve the inference capacity of the FISHO reasoner, thus allowing for relevant and comprehensive search automation and classification of fish.

With these two examples of the challenges faced during the development of the FISHO, one solution that may be adopted to further upgrade the FISHO is to create 2 types of classification, one based on traditional morphology-based taxonomic classification and the other based on modern of phylogenetic taxonomy. Through this approach, the ontology might have the ability to recognize fish specimens using both species and DNA characteristics. This solution may also be applied to other databases or recognition softwares having similar issues. Finally, we propose that future development of computational systems should utilize a variety of species specific data types to speed up the taxonomic classification processes.

Conclusions

An enduring and elusive challenge in biodiversity classification is to determine the numbers of species inhabiting the earth. It had been estimated that there are around 8.7 million species on land and sea, but many are still awaiting description (Mora *et al.*, 2011). This staggering number demonstrates the amount of effort that has been and still needs to be invested to properly classify and capture this biodiversity. As such, the pressure is on for taxonomists to expedite the process and for taxonomic databases to manage the voluminous amount of data accurately and with timely updates.

Scientific data, which refer to taxonomic information in this context, have limited usefulness if they are not read or discovered by others. It has been more than 200 years now since Linnaeus founded taxonomy. His research, and that of his counterparts, had resulted in many natural history drawings, identification keys, species descriptions, and monographs. However, such important records are almost untouched in this digital age. The way forward is to integrate technology with these traditional taxonomic knowledge base. Availability of such data in the online medium will promote secondary research using modern data science techniques, which may give birth to new knowledge and facilitate reproducible research. With the help of semantic data and ontology, digitized taxonomic resources could be made immediately accessible to the public and facilitate seamless integration of new taxonomic information.

Ecological Networks

Kazuhiro Takemoto and Midori Iida, Kyushu Institute of Technology, Fukuoka, Japan

© 2019 Elsevier Inc. All rights reserved.

Introduction

In the natural world, many species complexly interact with one another via various types of relationships (e.g., commensalism, amensalism, competition, mutualism, prey-predator relationship), and they compose ecosystems (Allesina and Tang, 2012). It is important to understand the function and stability against environmental perturbations (e.g., climate change) of ecosystems in the context of biodiversity maintenance and environmental assessment (Bascompte, 2010; Evans *et al.*, 2013; Pocock *et al.*, 2012). In computational biology, up until now, ecological networks have been mainly examined using theory (mathematical models such as Lotka–Volterra equations (Jansen and Kokkoris, 2003) describing the time evolutions of species populations). For example, May's pioneering theoretical works on the relationship between ecosystem complexity and stability (May, 1976; May, 1972) are interesting because ecosystem stability is related to biodiversity maintenance.

More recently, ecosystems have also been studied from a data analysis perspective. The development of field observation techniques and the improvement of infrastructure such as databases have increased the ecological data availability and have enabled large-scale data analyses of real-world ecosystems. In this context, *network science* plays an important role. Network science in ecology is called *network ecology*. In this article, we will overview the network ecology topic and the approaches to investigate ecological networks.

Network Ecology

Network science is a research area in which complex networks are studied, and it originates from graph theory (Barabási, 2013). Networks describe the relationships among elements, and are, thus, simple and powerful tools for describing complicated systems. The concept of networks is universal and can be applied to a wide range of fields (e.g., mathematics, computer science, economy, sociology, chemistry, biology). In recent years, considerable data on interaction has been accumulated. Thus, networks have become quite important for understanding real-world systems and extracting knowledge of complex systems. For example, network science has been applied to biology. The biomolecules of the living organisms such as proteins and metabolites undergo several interactions and chemical reactions which lead to the occurrence of various life phenomena. To understand the biological processes, it is important to obtain an understanding of the networks; thus, network biology (Barabási and Oltvai, 2004) and network medicine (Barabási *et al.*, 2011) have already attracted attention. Ecological communities are also represented as networks or graphs (so-called *ecological networks* in which nodes and edges correspond to species and inter-specific interactions, respectively). As the availability of ecological data has increased, network science has also been applied to ecology (Proulx *et al.*, 2005).

Ecological networks are often classified according to interaction types (e.g., mutualism and prey–predator relationship). The representative ecological networks are *food webs* and *mutualistic networks*.

Food webs indicate who eats whom, and they have discussed in ecology for a very long time (Kondoh *et al.*, 2010; Thompson *et al.*, 2012). Food webs are represented as networks in which nodes and edges correspond to organisms and trophic links (prey–predator relationships). It should be noted that food webs are generally represented as unipartite directed networks (Fig. 1(A)) because of predator–prey relationships which are direction-oriented. Food webs are often also called *antagonistic networks* and *trophic networks*. However, plant–herbivore food webs are represented as bipartite networks (Muto-Fujita *et al.*, 2017) defined as graphs having two different node sets.

Mutualistic networks are generally mentioned in the context of plant–animal mutualism. The representative mutualistic networks are *pollination networks* (plant–pollinator relationships) and *seed-dispersal networks* (the relationships between plants and animals that transport the plant seeds). The mutualistic networks are represented as bipartite networks (Fig. 1(B)) because mutualistic links are only found between two types of organisms (i.e., plants and animals) (Bascompte *et al.*, 2003; Olesen *et al.*, 2007).

Approaches

Searching for Non-Random Structural Patterns

Which factors determinate ecosystem stability is a long-standing question in ecology (see also Section Structure–Stability Relationship). Earlier theoretical studies (e.g., May, 1976, 1972) indicated that more complex ecosystems (i.e., larger and/or denser ecological networks) are less stable. However, this prediction is inconsistent with the fact that real-world ecosystems are complex. This is known as May's paradox. Resolving the paradox is a central topic in theoretical ecology. The paradox is expected to result from an assumption, in particular, the studies that considered that ecological networks are random for simplicity.

Fig. 1 A network representation of ecological networks. (A) A food web represented as a directed network. Nodes and directed edges correspond to species and prey–predator relationships, respectively. (B) A mutualistic network represented as a bipartite network. Square nodes and circle nodes are plants and animals. Edges are mutualistic relationships (pollination between plants and animals).

Fig. 2 Schematic diagram of nested structure and modular structure in bipartite networks.

However, is this assumption really sufficient in real-world networks? Network analyses of real-world ecological networks have found that the networks are not random. Specifically, real-world ecological networks are known to display two non-random structural patterns (**Fig. 2**). One structural pattern is the nested architecture (*nestedness*) (Bascompte *et al.*, 2003), a hierarchical structure in which the interaction pairs of a specialist species are included in those of another (generalist) species. In other words, the interaction partners of a specialist species are the subset of those of another generalist species. Another structural pattern is the modular structure (*modularity*) (Olesen *et al.*, 2007), a compartmentalized structure in which a number of dense sub-networks (modules) are weakly interconnected. Despite the correlation between them, these two structural patterns can provide complementary information on how interactions are organized in communities (Fortuna *et al.*, 2010). The degree of nestedness and modularity differ between food webs and mutualistic networks, in particular, the modularity of mutualistic

networks is typically lower than that of food webs, whereas the nestedness of mutualistic networks is generally higher than that of food webs (Bascompte *et al.*, 2003; Thébault and Fontaine, 2010). However, food web subnetworks are significantly nested (Kondoh *et al.*, 2010).

Structure–Stability Relationship

Non-random structural patterns (e.g., nestedness and modularity) are expected to influence ecosystem stability. In fact, nestedness plays important roles in increasing ecosystem stability in mutualistic networks (Bastolla *et al.*, 2009; Saavedra *et al.*, 2016, 2011), and it emerges as a result of an optimization principle aimed at maximizing species abundance (Suweis *et al.*, 2013). Modularity is a particularly important property because it is related to the robustness (Hartwell *et al.*, 1999). Thus, modularity is a significant property of biomolecular networks such as signaling networks (Takemoto and Kihara, 2013) and metabolic networks (Takemoto and Borjigin, 2011; Takemoto and Oosawa, 2012). According to these previous studies, modularity is expected to affect ecosystem stability. In fact, modularity can have moderate stabilizing effects, while anti-modularity can greatly destabilize ecological networks (Grilli *et al.*, 2016). Moreover, both nestedness and modularity influence ecosystem stability (Thébault and Fontaine, 2010). The contributions of nestedness and modularity to ecosystem stability differ between food webs and mutualistic networks. For example, increasing nestedness and/or decreasing modularity enhance the stability of mutualistic networks but reduce the stability of food webs. However, note that several recent studies have cast doubt on the importance of nestedness. For example, nested architecture can be more easily acquired than previously thought (Takemoto and Arita, 2010). A study based on numerical simulation indicated that biodiversity in mutualistic communities is described by the number of mutualistic partners a species has (i.e., node degree) rather than nestedness (James *et al.*, 2012). A theoretical study (Feng and Takemoto, 2014) supports this conclusion.

Effects of Environmental Factors on Ecological Networks

In the context of the structure–stability relationship, the effects of environmental or external factors on ecological networks are also important. Given that environmental factors can be sources of perturbation (e.g., rainfall, seasonal variation of climate), it would be expected that ecological networks have an optimal structure that maximizes the ecosystem stability against such perturbations. Macroecological studies are useful for evaluating the effects of environments on ecological networks (Trojelsgaard and Olesen, 2013), and they have enabled by the combined use of global-scale environmental data (see Section Impact of Global Warming on Ecological Networks for details). Such studies have demonstrated the climate change effects and human impacts on ecological network structure/ecosystem stability.

In the context of the structure–stability relationship, environmental factors influence the nestedness and modularity. Climatic parameters are linked to nestedness and modularity in mutualistic networks and food webs. For example, nestedness in pollination networks decreased with annual precipitation (Trojelsgaard and Olesen, 2013), whereas modularity in seed-dispersal networks and food webs increased with temperature seasonality (Schleuning *et al.*, 2014), and precipitation seasonality (Takemoto *et al.*, 2014), respectively. The type of climatic seasonality influencing the network structure differs among ecosystems. For example, network properties were mainly affected by rainfall seasonality in freshwater ecosystems but primarily by temperature seasonality in terrestrial ecosystems (Takemoto *et al.*, 2014).

The effects of climate change and human activities are more interesting in the context of biodiversity maintenance and environmental assessment. For instance, modularity and nestedness in pollination networks correlated with the historical rate of warming (Dalsgaard *et al.*, 2013) and human impacts (e.g., human population density, land use change, infrastructure development, and so forth) (Takemoto and Kajihara, 2016). Modularity declined and nestedness increased in seed-dispersal networks in response to human impacts (Sebastián-González *et al.*, 2015) and warming velocity (Takemoto and Kajihara, 2016). Food web nestedness increased and modularity declined in response to the global warming (Takemoto and Kajihara, 2016).

Finding Keystone Species

It is also important to characterize local properties (i.e., the characteristics of each node in a complex network) in addition to the global features of ecological networks such as non-random structural patterns. Specifically, finding important (keystone) species in ecological networks is challenging (Jordan, 2009). In this context, *Centrality* analysis is useful which is an important concept in network analysis because it helps in finding central (important) nodes in complex networks (Takemoto and Oosawa, 2012). It plays an important role in network biology and network medicine (Vidal *et al.*, 2011). In general, it is expected that hub species (i.e., species that interact with many other species) are important. However, recent studies encourage a reconsideration of the importance of hubs. For example, hubs can be classified into 2 types (Han *et al.*, 2004): party hubs that coordinate a specific functional modules and date hubs that play a role in intermediates between different specific functional modules. Moreover, they found that the effect of hub removals on complex networks is different between party hubs and date hubs. In particular, the removal of date hubs leads to a more immediate collapse of the networks than that by the removal of party hubs. This finding implies the importance of hubs bridging between different network modules. Therefore, module decomposition or community detection is also useful. In particular, a functional cartography method (Guimerà and Amaral, 2005), revealing patterns of

intra- and inter-module connections in complex networks, and the concept of bottlenecks (Yu *et al.*, 2007) is more useful to find important nodes. The bottlenecks are not always hubs. Importantly, the method can also evaluate the importance of inconspicuous (i.e., low-degree) nodes. In fact, a study examined pollination networks using this method, and it concluded that species serving as hubs and connectors should receive high conservation priorities (Olesen *et al.*, 2007). To detect important nodes based on the concept of bottlenecks, a number of centrality measures have been proposed (Takemoto and Oosawa, 2012). For example, an application of the PageRank algorithm for a website ranking of ecological networks is interesting. Such a centrality analysis is also useful for finding the importance of species for coextinction (Allesina and Pascual, 2009).

Illustrative Examples

In this section, we present some illustrative examples of network ecology approaches along with available databases and analysis tools.

Databases and Network Analysis Tools

Databases on ecological networks

Several databases on ecological networks are available, for example, 359 food webs are available in the GlobalWeb database (Thompson *et al.*, 2012; see Relevant Websites section). The Interaction Web DataBase (see Relevant Websites section) includes a number of ecological networks types, such as 27 food webs, 42 pollination networks, 12 seed-dispersal networks, 4 plant–herbivore networks, 4 plant–ant networks, 7 host–parasite networks, and 2 anemone–fish networks. The Web-of-Life Database (see Relevant Websites section) provides the data on a number of ecological networks: 143 pollination networks, 34 seed-dispersal networks, 34 host–parasite networks, 4 plant–herbivore networks, and 4 plant–ant networks. The Web-of-Life Database is useful for macro-ecological studies because the locations (i.e., latitude and longitude) of observation sites of the networks are also available in the database. Note that there are data duplications among the databases and the statistics as of October 4, 2017.

Network analysis tools

A number of network analysis tools are available to accelerate ecological network studies, in particular, the packages of the R-software (see Relevant Websites section). For example, the package *igraph* (igraph.org) is used for general network analysis (i.e. centrality analysis, community detection). A tutorial of *igraph* is available online at “Network Analysis and Visualization with R and *igraph*” link (see Relevant Websites section). The package *vegan* (see Relevant Websites section) and *bipartite* (see Relevant Websites section) are useful for analyzing mutualistic networks, represented as bipartite networks. The *nested* and *computeModules* functions in the *bipartite* package are used to calculate nestedness and modularity of bipartite networks, respectively. The functional cartography method is also available.

Environmental data

To explore the relationship between environments and ecological networks, environmental data at observation sites of ecological networks are needed. Several useful databases are available for this purpose. For example, the WorldClim database (Hijmans *et al.*, 2005; see Relevant Websites section) provides the gridded climate data with a spatial resolution of about 1 km². These data include annual mean temperature, temperature seasonality, annual precipitation, and rainfall seasonality (see Relevant Websites section). The data can be easily obtained using the R-package *raster*. In addition, the WorldClim database provides the past climate data (e.g., last glacial maximum climate conditions) estimated by the paleoclimate modeling intercomparison project. Climate change velocity is estimated by a comparison between the current and past climate (Dalsgaard *et al.*, 2013; Takemoto and Kajihara, 2016).

For human activities, the human footprint (HF) score from the global human footprint dataset compiled by the last of the wild project is available (Sanderson *et al.*, 2002). The HF score is provided with a spatial resolution of 1–km grid cells. According to the descriptions in the last of the wild database (see Relevant Websites section), HF scores are calculated by normalizing the human influence index defined as the sum of eight human activity-related variables: human population density, human land use change and infrastructure (built-up areas, nighttime lights, land use/land cover), and human access (coastlines, roads, railroads, navigable rivers).

The National Aeronautics and Space Act (NASA) Earth Data website (see Relevant Websites section) may be useful for obtaining other global environmental data.

Evaluating Significance of a Structural Pattern

As mentioned in Section Searching for Non-Random Structural Patterns, it is important to find non-random structural patterns of ecological networks. A comparison with randomized model networks was performed to evaluate the statistical significance of an observed network measure or structural pattern. Randomized networks are generated from a real-world network using edge-switching algorithms (Milo *et al.*, 2002) and configuration models (Catanzaro *et al.*, 2005; see also Takemoto and Oosawa, 2012). The significance of the network measure X was evaluated based on the Z-score: $Z_X = (X_{\text{real}} - X_{\text{rand}})/\text{SD}_{\text{rand}}$, where X_{real} is the

Fig. 3 The distribution of $NODF_{rand}$ obtained from 500 randomized networks compared to $NODF_{real}$.

network measure of a real-world network, $\bar{X}_{rand}$ is the average value of the network measure, and SD_{rand} is the standard deviation obtained from a large number of randomized model networks. Moreover, Z-scores are also used in the context of standardization (i.e., to allow comparisons among matrices).

As an example, we indicated the significance of nestedness in a pollination network (Mommott, 1999) (Fig. 3). Although several definitions of nestedness are proposed, we used the Nestedness metric based on Overlap and Decreasing Fill (NODF) metrics for evaluating nestedness (Almeida-Neto *et al.*, 2008). The NODF metrics is related to the proportion of shared interactions between species pairs over a bipartite network, and it ranges from 0 to 100. A null model based on configuration models (Bascompte *et al.*, 2003) was used to generate 500 randomized networks.

Comparison of Structural Patterns Between Different Types of Ecological Networks

Are structural patterns different between different types of ecological networks? Using a dataset (Takemoto and Kajihara, 2016), we compared nestedness and modularity among food webs, pollination networks and seed-dispersal networks (Fig. 4). We used the standardized NODF (Z_{NODF}) and standardized M (Z_M) for evaluating nestedness and modularity, respectively. M is a well-used modularity score, and it is defined as the fraction of edges that lie within, rather than between, modules relative to that expected by chance (Fortunato, 2010). M ranges from 0 to 1; a network with a higher M indicates a higher modular structure. We used the BIPARTMOD software (Guimerà *et al.*, 2007) (see Relevant Websites section) to calculate the modularity (M) of directed networks and bipartite networks because the BIPARTMOD software finds the maximum M based on simulated annealing to minimize the resolution-limit problem in community detection (Fortunato, 2010; Fortunato and Barthélemy, 2007).

Impact of Global Warming on Ecological Networks

As mentioned in Section Effects of Environmental Factors on Ecological Networks, it is hypothesized that non-random structural patterns are associated with environmental perturbations, given the structure–stability relationship. To test this hypothesis, using a dataset (Takemoto and Kajihara, 2016), we examined the relationship between warming velocity and nestedness/modularity in food webs (Fig. 5). We used the standardized NODF and standardized M to evaluate nestedness and modularity, respectively. Warming velocity (temperature change) is defined as the temporal climate gradient divided by the spatial climate gradient, with the temporal gradient in turn defined as the absolute difference between current and the last glacial maximum (LGM) climate conditions (see Takemoto and Kajihara, 2016 for details).

Results and Discussion

In the pollination network, the observed NODF score (42.8) was significantly higher than the average NODF score (34.5) obtained from the randomized networks (Fig. 3; $Z_{NODF} = 5.8$, $p = 7.2 \times 10^{-9}$ using the Z-test). This result indicated that the pollination network was nested than expected by chance. The significance of nestedness was generally concluded in pollination networks and seed-dispersal networks (i.e., mutualistic networks) (Fig. 4(A)). However, the significance of structural patterns was different between food webs and mutualistic networks. Food webs were less nested than expected by chance, while mutualistic networks

Fig. 4 Differences in nestedness (A) and modularity (B) among food webs, pollination networks, and seed-dispersal networks.

(pollination and seed-dispersal networks) are highly nested (**Fig. 4(A)**; $p < 2.2 \times 10^{-16}$ using the Kruskal–Wallis rank sum test). On the other hand, food webs were highly modularized (compartmentalized) while mutualistic networks were less modularized (**Fig. 4(B)**; $p = 8.2 \times 10^{-13}$ using the Kruskal–Wallis rank sum test). This result may be due to the fact that the contributions of nestedness and modularity to ecosystem stability differ between mutualistic networks and food webs, in that increasing nestedness and/or decreasing modularity enhance the stability of mutualistic networks but reduce the stability of food webs (Thébault and Fontaine, 2010).

A positive correlation between warming velocity and nestedness was observed (Spearman's rank correlation coefficient $r_s = 0.44$, $p = 2.7 \times 10^{-7}$). On the other hand, modularity was negatively correlated with warming velocity ($r_s = -0.30$, $p = 6.1 \times 10^{-4}$) (**Fig. 5**). Increasing nestedness and/or decreasing modularity reduced ecosystem stability in food webs (Thébault and Fontaine, 2010); as such, this result suggested that food-web stability decreases in response to environmental changes. However, more careful examinations are required. In macroecological studies, we need to remove any inherent spatial autocorrelation. In this context, a spatial eigenvector mapping modeling approach is useful (Takemoto and Kajihara, 2016).

Future Directions

Network ecology has scientific and societal impacts; however, it remains controversial.

Weighted Network Analysis

Ideally, ecological networks should be represented as weighted networks because of interaction weights, in particular, a different conclusion may be derived from comparisons between weighted and binary networks. For example, nestedness is statistically significant in binary networks but not in weighted networks (Staniczenko *et al.*, 2013). Temperature seasonality was correlated with the weighted version of modularity, but not with the binary version of modularity (Schleuning *et al.*, 2014). However, many

Fig. 5 Scatter plots of a network parameter versus warming velocity in food webs. Nestedness (A) and modularity (B).

of ecological network studies have considered binary networks (i.e., presence: 1, or absence: 0, of a given link) because the datasets include numerous binary data, and many software programs for network analysis generally assume binary networks. This is also because the definition of interaction weight is not uniform throughout the ecological-network datasets. The interaction weight assigned to a given species pair is based on the number of contacts they share. However, the weight need to be corrected (or normalized) for factors such as sampling effort (e.g., observation area and observation time) and species abundance. Such normalization methods differ among studies. Thus, database normalizations are needed (see Section Construction of Highly Normalized Databases).

Multiplex Network Analysis

A mixture of interaction types is essential for more realistic interactions although ecological networks have been generally classified according to the interaction types. In particular, the mixture of interaction types may contribute to increasing ecosystem stability (Allesina and Tang, 2012; Mougi and Kondoh, 2012). Network measures for multiplex networks should be considered in the future to evaluate ecological network structure under more realistic conditions. Multiplex networks consist of a set of nodes connected by different link types, and have been studied in the context of social network analysis (Hoang and Antoncic, 2003). Recently, multiplex ecological network analyses have also begun (Baggio *et al.*, 2016; Pilosof *et al.*, 2017).

Construction of Highly Normalized Databases

More highly normalized databases should be constructed. In particular, information on ecological networks (e.g., species taxonomy, ecosystem type, observed site, observed area, and time) should be summarized. For example, it is possible that sampling effort affects network parameters (e.g., nestedness and modularity) when considering the species–area relationship (McGuinness, 1984) which states that the number of observed species increases with the observed area. However, the relevant information on sampling effort is not often obtained because it is not always clearly delineated in the literature and databases. In addition, the effects of phylogenetic signals should be examined because several studies have reported that phylogenetic signals are weak in ecological networks (Rezende *et al.*, 2007; Schleuning *et al.*, 2014). However, ecological networks partly consist of species whose descriptions are unknown (i.e., they are expressed as species A and species B) or ambiguous. Moreover, a restricted understanding

of interspecific reactions (i.e., missing links) is a more serious limitation. To avoid these limitations, larger-scale and more highly normalized databases should be constructed, and it is especially important that data on weighted networks be expanded. In this context, data sharing (Parr and Cummings, 2005) is also important.

Linking to Dynamics

The relationship between network structure and dynamics (e.g., ecosystem stability) remains unclear. Alternative approaches are needed. Recently, the novel analytical framework revealed the universal relationship between the system's dynamics (coextinctions or cascading failures in ecological networks, in particular) and network topology (Gao *et al.*, 2016). In particular, the authors indicated that a single universal resilience function and parameter can characterize the behavior of different networks. Stochastic models for coextinctions in ecological networks are also useful (Vieira and Almeida-Neto, 2014). Such models are capable of simulating extinction cascades far more complex than those observed in network topology-based models. For example, the models produce complex extinction cascades in which species losses in one trophic level may lead to indirect additional species losses at the same trophic level, and they predicted extinction cascades to be more likely in highly connected ecological communities. However, the validity of these approaches is still debatable; thus, more careful examinations are required. The development of such novel network-based analytical frameworks remains an important topic.

Closing Remarks

This article has described the current understanding of ecological networks revealed through data analysis and theoretical studies. Networks are useful for extracting knowledge of complex ecosystems. Real-world ecological networks are non-random, and such non-random structural patterns are different among the ecological network types. Moreover, the non-random structural patterns influence ecosystems stability, and they are linked to environmental changes. Network ecology approaches enhance our understanding of ecosystem stability and the effects of environmental change on ecosystems. Considering that ecological networks have not been fully understood yet, network ecology is a research field with high future growth potential.

Biographical Sketch

Kazuhiro Takemoto received his doctoral degree in Informatics from Kyoto University in 2008 after earning his bachelor's and master's degrees in Computer Science from Kyushu Institute of Technology (Kyutech) in 2004 and 2006, respectively. After serving as a JSPS research fellow (2007–2009), a postdoctoral fellow at University of Tokyo (2009), Japan Science Technology Agency PRESTO researcher (2009–2013) and assistant professor at Kyutech (2012–2015), he is currently an associate professor at Kyutech (2015–). His research interests are network science, computational and integrative biology.

Midori Iida received her doctoral degree in Science from Ehime University in 2013 after earning her bachelor's and master's degrees in the university in 2008 and 2010, respectively. She is currently a postdoctoral fellow at Kyushu Institute of Technology (2013–). Her research interests are ecotoxicology, aquatic life science, and bioinformatics.

Dedicated Bioinformatics Analysis Hardware

Introduction

Recent years have seen a tremendous increase in the volume of data generated in the life sciences, especially propelled by the rapid progress of next-generation sequencing (NGS) technologies. For example, the sequence read archive (SRA) from NCBI which stores sequence data obtained from NGS technology now contains well over 10^{16} base-pairs (bps) of DNA sequence data and doubles in size roughly every 18 months. It is estimated that between one hundred million and two billion human genomes could be sequenced within the next decade (Stephens *et al.*, 2015) which will have a major impact on many areas of life in general with many applications in precision and personalized medicine as well as drug discovery (Schmidt and Hildebrandt, 2017).

This review provides an overview of the usage of GPUs, FPGAs, and dedicated hardware in bioinformatics. We provide some background information in Section Background/Fundamentals. In Section Applications we discuss a number of typical bioinformatics applications that can benefit from massive parallelism while Section Illustrative Examples focuses on two illustrative examples. We finish with a discussion, upcoming trends, and closing remarks in Sections Discussion, Future Directions, and Closing Remarks, respectively.

Bioinformatics is a wide field. We focus on sequence-based and structure-based applications. Further popular areas such as the usage of GPU/FPGA computing in systems biology, genome-wide analysis, or mass spectrometer data processing are outside the scope of our review.

Background/Fundamentals

Inherent to sequence-based approaches is a very common abstraction in bioinformatics – the representation of biopolymers (proteins, DNA, and RNA) as one-dimensional strings or sequences of characters. While this abstraction works surprisingly well for a wide variety of application scenarios, more detailed insight into bio-molecular function often requires more complex representations.

In structural or structure-based bioinformatics, molecules are represented as collections of atoms with properties such as element type, partial charge, covalent bonds, radius, and three-dimensional position and velocity in classical or semi-classical models, or by models of their quantum mechanical wave functions in quantum chemistry.

Even though sequences and structures are different molecular abstractions, both sequence-based and structure-based bioinformatics have the need for efficient implementations of core algorithms in common, albeit generally for different reasons (while sequence-based bioinformatics needs to scale to exploding experimental data set sizes, structure-based approaches generate tremendous amounts of floating-point computations). The traditional approach to implement bioinformatics applications is based on standard microprocessors (CPUs). Unfortunately, the compute performance provided by CPUs is often insufficient to meet current and future requirements. For example, it is projected that variant calling from NGS data alone requires around two trillion CPU hours by 2025 (Stephens *et al.*, 2015). Thus, bioinformatics data analysis shows the increased importance of computational techniques and the usage of high performance computing (HPC) infrastructures (Schatz, 2015).

Technology relevant for HPC applications comes in different variants, each with their own characteristics. Accelerator technologies such as Field Programmable Gate Arrays (FPGAs) and Graphics Processing Units (GPUs) can be an attractive option compared to large-scale compute clusters and clouds, especially in terms of price-performance ratio and energy-efficiency.

GPUs can provide around one order-of-magnitude higher peak performance compared to CPUs through massive fine-grained parallelism at a highly competitive price-performance ratio (Owens *et al.*, 2008). Using programming languages such as CUDA or OpenCL they can be used for general-purpose applications. While applications in structural bioinformatics are typically floating point-based and highly compute-intensive, sequence analysis algorithms are usually integer-based and more data-intensive. In order to realize an efficient GPU-parallelization, both careful algorithm design and optimized implementation are required.

Field programmable gate arrays (FPGAs) are programmable hardware chips mainly consisting of configurable logic gates and memory blocks (Compton and Hauck, 2002). FPGA configurations are generally specified using a hardware description languages such as VHDL or Verilog. FPGAs are particularly attractive for applications in cryptography and sequence analysis where relatively simple highly regular operations are performed on short integers. Thus, using FPGAs for analyzing large-scale sequence data offers a great opportunity for algorithm acceleration.

Finally, if monetary cost is not an issue, dedicated hardware can be designed for the problem at hand in the form of so-called application-specific integrated circuits (ASICs). These hand-tailored processors can achieve unparalleled efficiency and performance, but suffer from inflexibility with respect to alternative workloads.

Applications

BLAST

The most popular software to search a library of sequences with a query sequence is BLAST. BLAST is a family programs of which BLASTN (Nucleotide-nucleotide BLAST) and BLASTP (Protein-protein BLAST) are most widely used. The heuristics used consist of a pipeline of several stages, which have different characteristics (e.g., two-hit method in BLASTP vs. word-matching in BLASTN) but also contain common components.

Acceleration of BLAST on FPGAs and GPUs has received much attention. Mercury BLASTP (Jacob *et al.*, 2008) and Mercury BLASTN (Lancaster *et al.*, 2009) implement all stages of NCBI BLASTP and NCBI BLASTN. They achieve speedups of around one order-of-magnitude on a system with two Xilinx Virtex-II 6000-6 FPGAs compared to NCBI BLAST executed on two Opteron CPUs. The more recent CAAD BLAST (Mahram and Herbordt, 2015) reports a 5x speedup on a single Virtex-6 FPGA over a fully parallel implementation of the reference code on a modern multi-core CPU. Wienbrandt (2014) presents a BLASTP implementation that scales to 128 Spartan3-5000 FPGAs. Timelogic's Tera-BLAST (2017) is a commercial FPGA implementation of various BLAST algorithms. GPU-BLASTP (Vouzis and Sahinidis, 2010), CUDA-BLASTP (Liu *et al.*, 2011a,b), and cuBLASTP (Zhang *et al.*, 2015) are implementations of BLASTP on CUDA-enabled GPUs. G-BLASTN (Zhao and Chu, 2014) and HS-BLASTN (Chen *et al.*, 2015) report massively parallel GPU accelerations of BLASTN and MegaBLAST. The recent H-BLAST (Ye *et al.*, 2017) achieves speedups ranging between 4 and 10 on one K20x GPU over the sequential NCBI-BLASTP.

NGS Read Mapping

The *mapping* of NGS reads to a reference genome sequence is usually one of the first steps in many NGS data processing pipelines. Most existing read mappers (or aligners) are based on a seed-and-extend approach where short exact matches (seeds) are first identified using an index data structure. These seeds are then verified whether they can be extended to a full alignment. Approaches to accelerate read mapping can be categorized by the utilized indexing data structure.

Early GPU approaches including CUSHAW (Liu *et al.*, 2012) and SOAP3-dp (Luo *et al.*, 2013) are based on the Burrows Wheeler transform (BWT) with FM-index. This approach has a low memory footprint and thus can fit into the limited GPU global memory. Arioc (Wilton *et al.*, 2015) and PEANUT (Koster and Rahmann, 2014) are examples of more recent GPU-accelerated read mapper based on hash tables. nvBowtie is a GPU-accelerated of the popular Bowtie2 software built on top of the NVBio (NVIDIA, see Relevant Websites section) library achieving a speedup of up to 8 on a K80 GPU compared to Bowtie2 running with 20 CPU threads. BowMapCL (Nogueira *et al.*, 2016) is based on OpenCL instead of CUDA in order to support multiple heterogeneous accelerators reporting speedups between 2 and 7.5 on a single GeForce GTX Ti GPU compared to multi-threaded Bowtie and BWA. Chen *et al.* (2013) proposed a hash-based short read mapper for FPGAs. Houtgast *et al.* (2015) implemented an FPGA-accelerated as well as a GPU-accelerated (Houtgast *et al.*, 2017) version of BWA-MEM, which achieve roughly the same performance. Arram *et al.* (2017) leverage FPGAs to accelerated Bowtie2 and achieve a 28x speedup on a Maxeler MPC-X2000 node consisting of eight Altera Stratix-V FPGAs compared to multi-threaded Bowtie2 running with 16 CPU threads. Fernandez *et al.* (2015) reported a 12-fold speed gain on a Conway HC-2ex system compared to Bowtie running eight CPU threads.

Variant Calling

Variant calling is an important operation performed on the alignments returned by mapping NGS reads to a reference genome. GSNP (Lu *et al.*, 2011) is a GPU-accelerated version of SOAPsnv reporting speedups of around 40. Luo *et al.* (2014) leverages the power of GPUs to implement a pipeline consisting of read mapping, re-alignment and variant calling called BALSA. It is able to process 90 samples from the 1000 genomes project in around 3 days on a cluster with five GTX680 GPUs. The commercial DRAGEN platform provides FPGA-accelerated implementations of genome and transcriptome NGS analysis pipelines. Miller *et al.* (2015) report whole genome sequencing (WGS) on the DRAGEN system within 26-h time from blood sample to provisional diagnosis.

Denovo Assembly and Error Correction

While approaches for accelerating denovo genome assembly have been limited, the time-consuming pre-processing step for correcting errors in NGS reads has received considerable more attention. CUDA-EC (Shi *et al.*, 2010) was the first approach to speedup error correction (EC) on GPUs based on Bloom filters. DecGPU (Liu *et al.*, 2011a,b) improved this approach to GPU clusters. nvLighter is a GPU-accelerated re-engineering of the Lighter error corrector using the NVBio library (NVIDIA, see Relevant Websites section). Ramachandran *et al.* (2015) perform FPGA-accelerated EC achieving speedups of around 40x on a Stratix V FPGA compared to the CPU-based BLESS algorithm.

Multiple Sequence Alignment

Progressive alignment is a widely used but time-consuming approach for computing multiple sequence alignments (MSAs). MSA-CUDA (Liu *et al.*, 2009b) was the first GPU-implementation of all three stages of the ClustalW pipeline. CUDA ClustalW (Hung *et al.*, 2015) is an efficient GPU implementation of ClustalW v2 on multiple GPUs. G-MSA (Blazewicz *et al.*, 2013) accelerates the

T-Coffee algorithm to achieve around two orders-of-magnitude speedup. QuickProbs (Gudys and Deorowicz, 2014) is a variant of the highly accurate MSAProbs (Liu *et al.*, 2010b) algorithm suited for GPUs. A reconfigurable computing approach proposed by Oliver *et al.* (2005b) accelerates the first stage of ClustalW by computing pairwise alignments with a linear systolic array. Lloyd and Snell (2011) mapped the third phase onto FPGAs reporting a speedup of up to 150 versus a single core. Mahram and Herbordt (2012) accelerate ClustalW through pipelined prefiltering on a FPGA.

Molecular Force Fields

A fundamental abstraction in structural bioinformatics is the notion of a molecular force field. In principle, simulating molecular behaviour at atomic resolution would require modelling quantum mechanics, as non-classical effects are crucial at such length scales. Such models, however, have very large computational demands. Molecular force fields address this problem by prescribing collections of interatomic interaction energies that would lead to a behaviour compatible with quantum mechanics and experimental evidence. For example, a quadratic energy component can be used to model covalent bonds, as long as the expected length deviations are not too large. More realistic models for larger deviations can be obtained using higher order polynomials or exponential models, albeit at greater computational cost.

Force fields contain two different classes of interaction: *bonded* and *non-bonded*. Bonded interactions occur only between atoms sharing a covalent bond, while non-bonded ones (typically van-der-Waals interactions and electrostatics) can occur between any pair of atoms. Since the number of bonds per atom is bounded by a small number, the number of bonded interactions is linear in the number of atoms in the system. Non-bonded interactions, on the other hand, grow quadratically and, hence, typically dominate computational cost of force field evaluations.

Depending on the system under consideration and the required accuracy, more sophisticated types of force fields may be needed, such as polarizable (Baker, 2015) or reactive (Farah *et al.*, 2012). On the other hand, force fields may be coarse-grained over collections of atoms to save on computational cost (Barnoud and Monticelli, 2015).

Molecular Docking

Molecules exert influence on one another through physical interactions. To regulate a system as complex as a living cell, or even a multi-cellular organism, at the molecular level requires a high degree of specificity: a molecule intended to activate or suppress a particular target can not be allowed to blindly interact with any other protein in the vicinity. The physical origin of this specificity is the short range and relatively weak strength of the pair-wise interactions: to exert a noticeable influence, many pairs of atoms on the surfaces of both molecules need to come into close contact. This implies a degree of geometric compatibility. To use Emil Fischer's famous image, one molecule fits like a key into the other molecule's lock (Fischer, 1894), or more appropriately using Koshland's induced fit-model (Koshland, 1958), like a hand into a glove that is slightly too small, modifying its shape along the way.

Predicting whether a given molecule could bind to an active site of another, and with what binding strength, is of great interest to many fields of science and industry, such as drug design. In principle, the structure and binding strength of such molecular complexes could be studied using molecular dynamics (MD), given suitable force fields. The computational effort required for this task, though, is currently out of reach outside of dedicated MD hardware such as Anton 2. However, in many cases it might not be necessary to study the full dynamics of molecular complexes to predict molecular binding. Empirically, we often find that one geometric arrangement of such a complex has significantly lower energy than others and, hence, dominates the partition function of the system (Rarey *et al.*, 1996). Predicting this structure and approximating its binding energy is the task of docking algorithms.

In essence, docking methods are optimization procedures for some scoring function approximating the binding strength with respect to the molecular degrees of freedom. In rigid docking, only six degrees of freedom are optimized: the translation and rotation of one of the partners. In reality, though, molecules are non-rigid and can undergo flexible rearrangements upon binding, which greatly increases the dimensionality of the optimization problem as well as the number of local minima.

Most work on the GPU-based acceleration of flexible docking algorithms was devoted to porting heuristic global optimization approaches, such as genetic algorithms, simulated annealing, or differential evolution, or to vectorize the interaction energy calculations required for these methods (Korb *et al.*, 2011). Autodock (Morris *et al.*, 2009), for instance, has seen several user-contributed ports to the GPU, some of which are quite popular. In addition, Autodock has been ported to FPGAs (Pechan and Feher, 2011), yielding significant speed-up compared to a CPU-implementation, but being more or less on par with a GPU variant.

Illustrative Examples

Pairwise Sequence Alignment

For pairwise sequence similarity computation, the Smith-Waterman (SW) algorithm, the Needleman Wunsch (NW) algorithm, and their variants are widely used. They compute the optimal local, global, or semi-global alignment of two sequences under a given scoring scheme by means of dynamic programming (DP). The associated time complexity proportional to the product of sequence lengths makes this method time-consuming in many application scenarios. Consequently, parallelization approaches

have been proposed for a variety of hardware platforms. We compare the achieved performance in terms of billion cell updates per second (GCUPS).

Early solutions based on dedicated hardware were already proposed in the 1980s. [Lipton and Lopresti \(1985\)](#) proposed one of the first designs based on a systolic array implemented on an ASIC. Systolic array approaches are typically based on a linear array of simple processing elements (PEs) working in lock-step. The DP matrix is typically calculated using a *wavefront* scheme, whereby in every clock cycle a minor diagonal of the DP matrix can be calculated in parallel.

Consider two sequences S_1 and S_2 of length l_1 and l_2 . Assuming there are l_1 PEs each storing one character of S_1 , then we can compute the whole DP matrix in $l_1 + l_2$ time steps instead of $\mathcal{O}(l_1 \cdot l_2)$ on a single processor. If the number of PEs is less than the sequence length, a suitable partitioning scheme needs to be implemented.

FPGA-based solutions typically implement the systolic array approach on reconfigurable hardware instead of an ASIC. An early solution for DNA sequences using linear gap scoring by [Hoang and Lopresti \(1992\)](#) used a SPLASH board consisting of 32 Xilinx XC3090 FPGA chips to implement a linear of 248 PEs to achieve 0.27 GCUPS. [Oliver et al. \(2005a\)](#) proposed a systolic array of 252 PEs to scan a database of protein sequences with a query sequence using affine gap penalties and achieved 5.8 GCUPS on a single Virtex II XC2V6000 FPGA. [Zhang et al. \(2007\)](#) further improved the PE design to achieve 25.6 GCUPS on an Altera Stratix II FPGA. [Benkrid et al. \(2009\)](#) improved the flexibility with respect to supporting different sequence types and scoring schemes by implementing a parameterized SW algorithm FPGA-based accelerator. Recent work by [Xia et al. \(2017\)](#) extends the design from a score-only alignment computation to performing backtracking on a linear systolic array to achieve a performance of 106 GCUPS using 512 PEs on a Xilinx XC7VX1140T FPGA.

SW has also been implemented on a number of commercial FPGA systems. [Wienbrandt \(2014\)](#) reports 6020 GCUPS for aligning DNA sequences on the SciEngines RIVYERA S6-LX150 platform equipped with 128 FPGAs of type Xilinx Spartan6-LX150. [Vermij \(2011\)](#) achieves a performance of 460 GCUPS on the Convey HC1 system composed of four XC5VLX330 FPGA chips for SW without backtracking. Another commercial solution is from Timelogic (see Relevant Websites Section).

The first implementation of SW using CUDA was proposed by [Manavski and Valle \(2008\)](#) who achieved a performance of up to 3.6 GCUPS on a GeForce 8800 GTX. CUDASW++ 1.0 ([Liu et al., 2009a](#)) considerably improved performance to 16 GCUPS on a GeForce GTX 295 by a more careful consideration of the GPU memory hierarchy and the introduction of the inter-task parallelization approach where each CUDA thread computes a distinct alignment of a protein sequence database search task. The successor versions CUDASW++ 2.0 ([Liu et al., 2010a](#)) and CUDASW++ 3.0 ([Liu et al., 2010a](#)) further improved performance to 29.7 GCUPS on a GeForce GTX 295 and 185.6 GCUPS on a dual-GPU GeForce GTX 690, respectively. SWHybrid ([Lan et al., 2017](#)) is currently fastest CUDA implementation of SW-based protein database search achieving close to 300 GCUPS on a GeForce GTX 1080.

CUDAlign focuses on the computation of a single pairwise alignment of long (chromosome-length) DNA sequences. CUDAlign 1.0 ([Sandes and Melo, 2010](#)) calculates the DP matrix with the wavefront method and achieved a performance of 20.4 GCUPS on a GeForce GTX 280. CUDAlign 2.1 ([Sandes and Melo, 2013](#)) incorporates the retrieval of optimal local alignments in linear space with a performance 58.2 GCUPS on a GeForce 560Ti. The latest version ([Sandes et al., 2016](#)) achieves 10,370 GCUPS on a cluster with 384 GPUs for computing exact chromosome-wide DNA alignments.

Molecular Dynamics

Today, molecular dynamics (MD) simulations clearly belong to the most important computational techniques to study molecular properties ([Karplus and McCammon, 2002](#)). Starting from an initial configuration (i.e., position and velocity vectors for every atom in the system), a chemical parametrization (i.e., information about the chemical type for each atom) and a molecular force field, it solves for the classical equations of motion of the involved particles, with suitable modifications to achieve, e.g., constant temperature or pressure ([Rapaport, 2004](#)).

Integrating the equations of motion requires very small time steps, leading to large numbers of iterations to simulate biologically relevant time scales. Since system sizes can become quite large and since the number of non-bonded interaction evaluations grows quadratically, computation of such pairwise interaction energies typically dominates MD running times. Using increasingly long simulations of increasingly large systems with increasingly complex force fields hence leads to a growing demand for computational resources. Consequently, MD codes made use of GPU accelerators almost immediately after NVIDIA introduced CUDA in 2007 ([Stone, 2007](#); [Liu et al., 2008](#)). Today, all practically relevant MD implementations are GPU-accelerated, and in many cases scale well to multi-GPU setups.

A fully featured MD application is a complex, often modular, system with components that cover the whole MD pipeline from input preparation up to trajectory analysis. Porting the entirety of this pipeline to the GPU would hardly be suitable. Hence, modern MD codes provide GPU-accelerated implementations for time-critical parts of the pipeline that vectorize well and typically cover the majority of the computational work. Most vectorization efforts focus on the computation of non-bonded interactions, which are further decomposed into short-range and long-range interactions depending on the distance between the two interacting atoms.

Considering the functional form of the van-der-Waals interaction, which very quickly saturates to zero with distance, it is often possible to neglect all van-der-Waals terms between atoms at a distance beyond a user-defined threshold (optionally, the terms can be smoothly pulled to zero in a small region just below the threshold using a switch-off function) and hence treat these as short-ranged interactions only. For electrostatics, though, this approximation is often unsuitable. The most popular method to handle these interactions computationally is the so-called *particle mesh Ewald* (PME) summation ([Darden et al., 1993](#)), which separates the sum of all pairwise electrostatic interactions into a short-ranged and a long-ranged part as described above. The first part converges

quickly in real space and can hence be directly computed. To parallelize the second part, three different strategies can be employed (Rovigatti *et al.*, 2015):

1. Atom-decomposition, where each compute unit receives a block of atoms and computes all interactions of each atom in the block,
2. Force-decomposition, where all potentially interacting atom pairs are distributed over compute units, and
3. Space-decomposition, where a compute unit calculates the interactions of atoms within a certain spatial domain.

Atom-decomposition is currently the most popular approach on the GPU by far, implemented, e.g., in GROMACS, NAMD, or HOOMD-blue, even though force-decomposition might be preferable in some cases (Rovigatti *et al.*, 2015).

The second term of the above decomposition (long-ranged contributions to non-bonded interactions) converges slowly in real space, but quickly in reciprocal- or Fourier space. For periodic boundary conditions, this suggests to use fast Fourier transform algorithms on charge- and potential grids to convert them to Fourier space where suitable cut-offs enable efficient computation of the interaction contributions. While PME reduces computational effort on long-range interaction from $\mathcal{O}(n^2)$ to $\mathcal{O}(n \log(n))$, it is harder to parallelize than pairwise interaction summation due to non-negligible communications overhead. Hence, many MD packages, such as GROMACS (Pall and Hess, 2013; Pall *et al.*, 2015) or YASARA (Krieger and Vriend, 2015) use GPU acceleration only for the short-range contributions while keeping the rest (including PME) on the CPU which, incidentally, allows to keep CPU and GPU busy simultaneously. Other packages such as AMBER PMEMD (Götz *et al.*, 2012; Salomon-Ferrer *et al.*, 2013), ACEMD (Harvey *et al.*, 2009a,b), or HOOMD-blue (Anderson *et al.*, 2008; Glaser *et al.*, 2015) report that more than 90% of their computational workload is offloaded to the GPU.

When porting MD codes to accelerators, a further challenging complication arises from inherent numerical instabilities (e.g., through cancellation effects in summing over many small interactions). As shown by Colberg and Höfling (2011), single precision floating point calculations are insufficient even in simple situations using only Lennard-Jones potentials. While modern GPUs can handle double precision floating point computations reasonably well, albeit at the cost of greatly reduced performance. Hence, modern MD code often uses what is known as *mixed* precision or SPDP-mode (Götz *et al.*, 2012), where only sensitive operations are computed in double precision. Alternatively, fixed-point integer arithmetic or even extended precision can be used as a replacement for double precision in so-called SPFP-mode (Le Grand *et al.*, 2013) or SPXP-mode (Thall, 2006).

All this effort seems to be justified in practice. According to a white paper by NVIDIA, running at least part of the code on the GPU typically leads to speed-ups of 3x to 8x when compared to multi-threaded CPU implementations.

Considering the enormous compute requirements of MD simulations, it is not surprising that other kinds of accelerator hardware besides commodity graphics cards have been and are still being actively investigated. FPGA-based solutions such as Yang *et al.* (2007), Khan *et al.* (2013), Waidyasooriya *et al.* (2016) have repeatedly proven to yield significantly better performance than CPU-only code, but seem to suffer from sub-optimal floating point performance, in particular for those parts where double precision is required. The importance of MD as an indispensable tool for molecular studies even justifies the enormous cost of designing special-purpose MD ASIC solutions. RIKEN's MDGRAPE-4 system (Ohmura *et al.*, 2014) consists of 512 specially designed systems-on-chip (SoC), each of which has 64 pipelines for the computation of non-bonded interactions, running at 0.8 GHz and 65 Ten-silica Xtensa LX configurable processor cores with single-precision floating point units, clocked at 0.6 GHz, for the remaining calculations. Each SoC has a peak performance of 51.2 billion interaction computations per second. Optical transmitters and receivers are used for internode connections.

D.E. Shaw Research's (DESRES) Anton-architecture (Shaw *et al.*, 2008, 2014) in its second iteration is the first platform that was able to simulate several microseconds per day on systems composed of millions of atoms. All parts of the simulation pipeline are handled by the ASICs without resorting to general purpose commodity host processors. To fully leverage the system, DESRES also developed new MD algorithms adapted to the strengths of the system. The Anton 2 systems in operation consist of 512 ASIC nodes, each of which dedicates about one quarter of its die area to the computation of pair-wise interactions and additionally contains 66 general purpose programmable cores. Each ASIC is clocked at 1.65 GHz.

As demonstrated by the Anton system, the ability to routinely study protein behaviour at the micro- or even millisecond range is truly transformative, both for understanding general principles of biochemistry and protein organization and for dedicated biological or pharmaceutical applications (Chung *et al.*, 2015; Hu *et al.*, 2015; Pan *et al.*, 2017).

Discussion

In sequence-based bioinformatics the usage of GPU/FPGA/dedicated hardware is driven by the enormous progress of NGS technologies. Typical algorithms often rely on combinations of integer-intensive computations (such as dynamic programming for alignments) or big data techniques (such as large-scale index data structures). As many applications involving a single genome have already been parallelized, we are starting to see first acceleration approaches for analyzing *metagenomic* NGS data. MEGAHIT (Li *et al.*, 2016) assembles large and complex metagenomic datasets using a parallel algorithm for constructing succinct de Bruijn Graphs on GPUs while (Kobus *et al.*, 2017) perform metagenomic read classification on GPUs.

On the other hand, structural bioinformatics models biomolecules as three-dimensional objects with non-trivial and often dynamic geometry. It relies on concepts from computational physics, such as interaction energies and force fields, and from computational geometry, such as geometric queries and comparisons. Such models are typically based on floating-point

computations, often even at double precision. With increasing system sizes, simulation time steps, and model accuracy, the required amount of floating point operations grows immensely. Hence, structural bioinformatics quickly adopted accelerator technologies. Here, we have discussed some of the typical application scenarios focusing on MD and docking.

Compared to MD, using accelerators for docking has received considerably less attention. In fact, not all docking methods seem to map well to GPUs or FPGAs at all. One area that does profit significantly from GPU acceleration is rigid docking, which today is typically only considered suitable as part of a larger pipeline including flexibilization steps. Many rigid docking algorithms are based on computing correlations through multiplication in Fourier space, as pioneered by Katchalski-Katzir *et al.* (1992). FFT computation can easily be offloaded to the GPU, which has been used to speed up docking based on spherical harmonics (Ritchie and Venkatraman, 2010) or in the classical Katchalski-Katzir sense (Ohue *et al.*, 2014). In addition, the code has been ported to Intel's MIC architecture, where it was found to perform less well than on GPUs (Ohue *et al.*, 2014).

Future Directions

Programming of massively parallel accelerators can still be cumbersome. Implementing hand-optimized algorithms from scratch using languages like CUDA can be time-consuming since it requires a deep understanding of GPU architectures. However, this might change with the availability of highly optimized libraries and the advancements of pragma-based languages such as OpenACC. Furthermore, a major hurdle in taking up FPGA-based systems can be their programming complexity, leading to long software development cycles. Furthermore, application software is often not compatible across different FPGA generations. However, the recent development of higher level programming languages such as OpenCL for FPGAs and the availability of associated libraries offer an opportunity to write more portable yet efficient code.

Bioinformatics is becoming increasingly data-intensive which also implies an increased application of *deep learning* techniques (Ching *et al.*, 2017). Central to these techniques is large performance gains on parallel hardware such as GPUs or FPGAs. A recent example is *DeepVariant* (DePristo and Poplin, 2017) a tool for variant calling from NGS data that trains a highly complex neural network from MSAs.

However, increasingly complex neural networks and data sets require an even higher performance which motivates the recent development of ASICs (such as Google's Tensor Processing Unit (TPU)) or special functional components (such as the integration of Tensor cores in Volta GPUs). Thus, we can expect the regular usage of such hardware in bioinformatics analysis in the near future.

Closing Remarks

In this article we have surveyed the usage of parallel accelerator solutions for sequence-based and structure-based bioinformatics. State-of-the-art tools based on GPUs, FPGAs, or even ASICs can provide significant speedups compared to traditional CPU-based solutions. Since biological data sets continue to increase rapidly this approach provides a promising future direction to address the *big data deluge* challenge in the 'omics' sciences.

Biographical Sketch

Bertil Schmidt is tenured Full Professor and Chair for Parallel and Distributed Architectures at the University of Mainz, Germany. Prior to that he was a faculty member at Nanyang Technological University (Singapore) and at University of New South Wales (UNSW). His research group has designed a variety of algorithms and tools for Bioinformatics mainly focusing on the analysis of large-scale sequence and read datasets. For his research work, he has received a GPU Research Center award, GPU Education Center Award, CUDA Academic Partnership award, CUDA Professor Partnership award and Best Paper Awards at IEEE ASAP 2015 and IEEE ASAP 2009.

Andreas Hildebrandt is tenured Full Professor and Chair for Bioinformatics and Software Engineering at Johannes Gutenberg University Mainz in Germany. Previously, he was the head of the independent junior research group on protein–protein interactions and computational proteomics at the Center for Bioinformatics of Saarland University. His main research interests include structural bioinformatics, computational proteomics and computational systems biology, where his group develops and applies novel techniques and program packages. He is also one of the core developers of the BALL library.

Computational Pipelines and Workflows in Bioinformatics

Background and Fundamentals

Bioinformatic analyses aim to extract biological insights from raw data. Tenable approaches to such goals must be composed of discrete ordered steps, performed either in serial or in parallel. These steps must be communicated to other scientists, and generalized to accept both new biological samples and parameters. In many cases these steps, or *transformations*, have traditionally been performed by compiled software designed for Unix-compatible operating systems on distributed grid or cluster hardware at large academic and commercial institutions. As scientific computing has matured and borrowed from the greater technology community, this approach is evolving to further abstract out both hardware and operating infrastructure using portable, scalable, and expressive software.

Modern bioinformatics has been largely dominated by sequence analysis, whose processing and organizational demands has catalyzed the growth of pipelines and workflows in a field that has witnessed an explosion in throughput over the last two decades – from capillary gel electrophoresis systems (ABI 3700) capable of sequencing 300 kbp per day in 1999 (Mullikin and McMurry, 1999) to a sequencing by synthesis (SBS) machines capable of sequencing 16 whole human genomes (49.6 bpb; Illumina NovaSeq 6000) at a depth of 30x – a 165,333% increase. However, virtually every -omics subfield, as well as other life sciences and physical sciences, deal with the same need to formalize ad-hoc processes for the purposes of robustness, growth, transparency, and reproducibility.

The terms “pipelines” and “workflows” are used somewhat interchangeably, although conventionally a pipeline is a narrower description of a file transformation process, while a workflow can refer to any set of processes that encompass multiple goals and sometimes manual steps, even those in the laboratory.

Several disparate and changing elements – tools, pipeline frameworks, data and metadata standards, programming languages, notebooks, computational infrastructure – make up the “workflow landscape”. In particular three developments – the cloud, containerization, and semantic encoding – are rapidly changing how modern bioinformatic workflows are created. These are continue to evolve with the aim of improved scalability, accessibility, transparency, and perhaps most importantly, reproducibility.

The process of converting existing analyses into workflows catalyzes the modularization of steps common to many analyses, such that individual steps or entire pipelines can be reused for similar experiments with minimal modifications. A tangentially related aspect of this modularization is the formal introduction of common steps in machine learning workflows such as feature engineering, training, validation, testing, and optimization. The efficient dispatch of processing necessary for high-throughput analysis, processing thousands of samples and millions of data points, is an evolving focus of modern pipeline frameworks, and will be discussed in terms of scalability and computational runtime as well as in development time and handholding.

Scalability in workflows has been tackled from two sides of the high performance computing – one side the maturing use of cloud platforms to quickly deploy jobs on rented on-demand virtualized computing infrastructure using a variety of traditional cluster batch queueing systems, cloud-aware batch schedulers, container management systems, and serverless computing services. The other side is the development of distributed computing environments for big data, such as Apache Spark which can leverage large clusters while presenting a seamless interactive programming session. While these efforts are not incompatible, cloud computing has engaged the evolution of workflows and workflow frameworks more than Spark by allowing existing executables and algorithms to scale without reimplementing, basically running unaware of the workflow that is driving them.

The primary goal of a workflow, regardless of its formal structure, is “narrow-sense reproducibility” – the automated replication of results given a set of input data and parameters. A secondary or auxiliary goal is broad-sense reproducibility (aka “reviewable research,” Stodden *et al.*, 2013), the transparent communication of a scientific experiment or train of thought which encompasses both the intent of an analysis and its underlying source code. Workflows connect the versioning, dependencies, and literate programming, to reproducibly produce results from data and metadata (Sandve *et al.*, 2013) in the narrow repeatable sense. Workflows will also play larger roles in broader senses of reproducibility – confirmable, generalizable, reviewable, auditable, verifiable and validatable – though these goals are dependent on semantic representations of workflows and integration with the larger scientific process, namely publishing (Hrynaskiewicz *et al.*, 2014). Ideally, future article reviewers will swap out both individual tools and data in a workflow attached to a submission to test its underlying scientific validity.

In the information sciences community, the concept of reproducibility is often discussed in terms of “provenance” (Kanwal *et al.*, 2017; Gil *et al.*, 2007). Provenance is defined by the W3C as “a record that describes the people, institutions, entities, and activities involved in producing, influencing, or delivering a piece of data or a thing” (Moreau *et al.*, 2013). In workflow circles provenance refers to the origins of both input data, tools, results, and intermediates.

An interesting review by Cohen-Boulakia *et al.* (2017) examines workflow systems in the context of *reproducibility-friendliness*, using real-world use cases as a means to explore the needs of researchers in terms of reproducibility, and the strengths and limitations of pipeline frameworks. The workflow specification, provenance tracking, and dependency management are compared in terms of scientific demands related to reproducibility. These include rapid integration of new tools, tool version tracking, workflow execution provenance trace, and workflow segment reuse. This group also distinguishes “levels of reproducibility” from

the increasingly broad senses of repeat, replicate, and reproduce, each introducing progressively more variation from the initial *in silico* experiment. The article concludes that more tools are needed to assist in semantic annotation of workflows and to take advantage of the provenance being generated in terms of both validation and discovery; many workflows are not modular enough to work in an interoperable manner (accepting intermediates from other workflows, for example). Other areas highlighted as having potential for improvement are integration with publications, and the development of more user-friendly and abstracted workbenches.

Accessibility and shareability of workflows is key to realizing the vision of enabling “open analysis” or “open research” – transmission of an entire workflow to another individual to be evaluated or reused without significant technical hurdles. This goes hand-in-hand with the goal of analytical democratization, allowing biologists and other non-specialists to build and use pipelines with their own data. In the life sciences, many of these goals have been formalized in manifests such as the FAIR principles (Wilkinson *et al.*, 2016) and are being actively pursued by various international consortiums such as GA4GH (The Global Alliance for Genomics and Health*, 2016), as well as government-funded efforts such as the NIH’s Big Data to Knowledge (BD2K) program, and NCI’s Cancer Genomics Cloud (Davis-Dusenbery, 2015). These initiatives and other like them seek to build shared workflow platforms on the massive data coordination that has taken place over the past two decades.

Systems and Applications

Toolkits

Bioinformatics tools that cater to novel experimental research methods tend to be composed of simple tools aggregated into “toolkits” with common data formats and syntax conventions that focus on a domain. To maintain flexibility, tools within toolkits can be used “a la carte”, enabling tools from other toolkits or user-developed tools to be swapped in, and can take on a variety of software language implementations. Popular toolkits include the Genomic Analysis Toolkit for variant analysis (McKenna *et al.*, 2010) as of version 3.6 composed mostly of Java .jar files, the Tuxedo suite, comprised of tools including Bowtie, TopHat, and Cufflinks, compiled executables for DNA-seq and RNA-Seq analysis (Trapnell *et al.*, 2012). Bioconductor, which is currently composed of 1383 R packages, supports many interrelated tools organized by “Views” and “Common Workflows” such as Differential Expression and Flow Cytometry, with an emphasis on recipes and use-case driven documentation (Gentleman *et al.*, 2004). Bioconductor is supported by a backbone of key classes and methods such as GenomicRanges, SummarizedExperiment (Huber *et al.*, 2015), and VariantAnnotation (Obenchain *et al.*, 2014).

Ready-made pipelines

Ready-made pipelines such as bcbio-nextgen (Guimera, 2012), omicspipe (Fisch *et al.*, 2015) and Churchill (Kelly *et al.*, 2015) are tightly bound collections of existing third-party tools. Such pipelines are typically driven by large configuration files and are designed to provide optimal settings and high performance for typical workflows, however they are not extensible in the sense that user-developed tools cannot be easily integrated which can limit their application in experimental settings. Some ready-made pipelines, such as recount2 (Collado-Torres *et al.*, 2017), are composed of purely of libraries used within programming environments such as R, which offer the advantage of remaining in an interactive session for the duration of a pipeline, although this limits scalability.

Some pipelines are built on existing pipeline frameworks (discussed below). These include Knime4Bio (Lindenbaum *et al.*, 2011) and KNIME4NGS (Hastreiter *et al.*, 2017), based on the Konstanz Information Miner (KNIME). META-Pipe (Robertson *et al.*, 2016) and deepTools (Ramírez *et al.*, 2014) are popular toolkits built for use within Galaxy server workbench.

Plummer and Twin (2015) compared three popular ready-made pipelines for processing 16s rRNA gene sequences to study bacterial phylogeny and taxonomy – MG-RAST (Meyer *et al.*, 2008), QIIME (Caporaso *et al.*, 2010), and Mothur (Schloss *et al.*, 2009). This study found large differences in usability and performance, as well as tertiary measures such as user support, visualizations, and overall robustness in terms of being able to stably accommodate a range of experimental scenarios and varying input quality as encountered in the field. Robustness is arguably the primary criterion that determines the longevity of a pipeline in the scientific community, and together with reproducibility are the two most important abstract properties for judging pipeline quality (Sztromwasser, 2014).

Pipeline frameworks

Pipeline frameworks, also known as workflow management systems (WMS), or scientific workflow management systems (SWfMS), provide structured means of expressing file transformations that are common to bioinformatics analyses. These provide several key advantages over their predecessors in terms of robustness, reusability, extensibility and scalability (Goble and De Roure, 2009).

Until recently, most basic bioinformatic pipelines were developed using scripting languages, either in a Unix shell or a high-level scripting language such as Perl or Python. In such a scheme, variables are used to represent files or parameters and loops to perform iterative processing. An alternative to used the build automation tool, Make (Stallman and McGrath, 2002, described below), which provides a means of representing a dependency graph in terms of filename suffix wildcard recipes. Parameterization and dependency graphs, the descendants of scripts and Makefiles, have been universal components of all modern pipeline frameworks.

The dependency graphs described above, more precisely understood as directed acyclic graphs (DAGs), can represent both serial and parallel tasks and file dependency order. DAGs serve as the conceptual logic underpinning all workflows and are useful

as a visual representation as well as a functional map. The means by which DAGs are created distinguishes modern bioinformatic pipeline frameworks. DAGs are created either by the workflow itself, inferred from filename extensions or explicit inline task dependencies, or by the user, who may use a formal markup such as XML, a domain-specific shorthand, a full-featured language, or using a graphical user interface. Regardless of their origins, DAGs enable the internal workflow engine to determine which unfinished dependencies are needed to complete a task and which can be run in parallel.

A review by Leipzig categorizes frameworks using three criteria: using an implicit or explicit syntax, using a configuration, convention or class-based design paradigm and offering a command line or workbench interface (Leipzig, 2016). While these categories are broad and do not address myriad novel features developed by individual projects, the taxonomy is useful for understanding the major types of pipeline frameworks.

Implicit and explicit DSLs

Implicit frameworks can trace their lineage to the Make, a compile build tool designed in the 1970s as a domain-specific language. Make offers a set syntax consisting of symbols which relate files with different filename suffixes into implicit wildcard pattern rules, which define how these files can be transformed into one another. As such, Make can produce any file for which a rule chain exists. Make is highly dependent on file modification dates in order to assess necessary tasks. Crucial to the success of Make and other implicit frameworks is *reentrancy* – the ability to stop and resume the progress of a pipeline at any stage without penalty. Files that are already completed are not remade, but new samples introduced as input are processed. Reentrancy is indispensable during pipeline development, when errors are frequent, but is also useful for quickly recovering from unexpected events in production, as well as bypassing redundant tasks as projects that grow both in scale and scope. Implicit frameworks such as Snakemake (Köster and Rahmann, 2012) and Nextflow (Di Tommaso et al., 2017) augment the Make approach with support for full featured programming languages, Python and Groovy respectively.

Snakemake remains true to the conventions introduced by Make, in that pipelines are composed of explicit rules with target inputs (usually lists of files), and implicit wildcard rules which describe file transformations. While Python functions can be used as inputs, allowing databases or other actors to be sources of filenames, the general approach is file-centric. This reliance on file naming can necessitate a number of lookup functions when there is no clear suffix chain to associate inputs and outputs, as may happen when processing files named with universally unique identifiers (UUIDs). Nextflow introduces *channels* which hold file types shared between tasks, obviating the need to carefully tag intermediates with complex file suffix name schemes. Inputs and outputs in Nextflow are typed values, offering greater flexibility in terms of holding results in memory while still retaining reentrancy through caching.

Rather than rely on inputs, outputs, and generalized rules, *explicit frameworks* link *tasks* in a set order specified by the user. This approach is more intuitive to some whose conception of a pipeline does not deviate from a set script, but limits the flexibility of the pipeline to produce target files not initially anticipated by the user.

Configuration frameworks

We consider domain-specific languages (DSL) to use a “conventional” design paradigm, whereby the DAG is formed by following syntax conventions formed by the DSL and the underlying language, with an aim to reduce the overall typing load on the developer. A more structured approach is to demand a configuration file formatted in a markup language such as XML or JSON, with little or no embedded code.

Configuration frameworks are always explicit. In addition, they also strongly distinguish workflows from provenance. The respective terms assigned are “workflow templates” and “workflow runs” – a workflow run having all variables assigned and serving as a log of steps that are performed in the creation of an output.

Of course, workflow configurations can themselves be generated by scripts, various wizards both graphical and command line, or APIs, but they must be validated and loaded using strict parsers. This leaves little room for inline on-the-fly conditional logic based on input itself, often called “dynamic branching”, for example skipping corrupt files or switching sensitivity/specificity parameters.

Established configuration frameworks such as Pegasus (Deelman et al., 2005), are often tightly coupled to an existing execution engine, such as Condor (Thain et al., 2005), which enables efficient job scheduling but at the expense of portability. Modern configuration frameworks, such as Cromwell from the Broad Institute (Voss et al., 2017), support a number of execution engines and schedulers, both for in-house clusters and the cloud.

Workbenches

Workbenches typically offer a graphical canvas that allows users to connect nodes (representing tasks) with edges (representing parallel or serial data flow). Open source server workbenches can be installed locally or in the cloud. With over 1500 citations, Galaxy (Goecks et al., 2010) is arguably the most popular bioinformatics workbench. Galaxy is designed to be run on a local cluster or in the cloud. Knime (Berthold et al., 2009), Taverna (Wolstencroft et al., 2013), Vistrails (Callahan et al., 2006), and Kepler (Ludäscher et al., 2006) can be installed on a desktop computer but offer server and cloud-based execution. Commercial cloud-based workbenches such as DNANexus, SevenBridges, and Illumina’s BaseSpace are remotely managed, Software-as-a-Service (SaaS) installations, which provide private accounts and abstract the provisioning of underlying cloud platforms for usability. Developments in object storage such as Amazon Web Services (AWS) Simple Storage Service (S3) buckets have allowed researchers some autonomy in how their data is owned and managed.

Some *collaborative analysis platforms* combine the mechanics of canvas workbenches with an existing suite of reference data, highly customized reports, and comparative samples, typically focused to maximize relevant results in a specific domain. One

example is Cavatica, a joint project of Seven Bridges Genomics and Children's Hospital of Philadelphia to accelerate pediatric cancer research by encouraging data sharing with the open use of standards-compliant tools and workflows and visualizations developed for the cBioPortal (Gao *et al.*, 2013).

For high throughput analyses there is usually a need to automate data management away from the graphical user interface using local command line dispatch. This is normally supported using APIs. Projects such as BioBlend (Sloggett *et al.*, 2013) provide tools to remotely manage CloudMan (Afgan *et al.*, 2010) cloud instances which host Galaxy workflows. Other platforms such as Arvados (Amstutz *et al.*, 2016) and Cyverse (Devisetty *et al.*, 2016) provide support for API-driven workflows and a large data collection that can be browsed using dashboard tools.

Common workflow language

Because of the highly linked nature of these operations, workbenches require strongly typed tool definitions and workflow descriptions to perform in a robust manner. The sheer number of bioinformatic tools and frameworks warranted a level of standardization in order to reduce redundancy and enhance portability of tools and workflows. The proliferation of pipeline frameworks, each with its own idiosyncratic syntax for defining tool inputs, outputs, and parameters, presents frustrations for both users and developers. An effort spearheaded by developers at commercial cloud workbench platforms has developed a standard format for defining both workflows and tool definitions that can be used by any configuration-based framework. The Common Workflow Language (CWL) is a multi-vendor consortium that has developed a configuration-based standard for interfacing with command-line software, describing workflows, and adding semantic annotation to these elements.

Two important technologies being used by CWL are JSON-LD, a linked human-readable data format that provides semantic encoding to elements such as tools, inputs, and outputs, and Docker (see below), a containerization layer that provides isolation and a consistent environment for tools. This effort has spawned an entirely new schema validation system supporting JSON-LD (SALAD), the cwl-viewer for visualization, and a number of APIs for producing CWL programmatically (Figs 1 and 2).

Class-based frameworks

Class-based frameworks dispense with the symbolism of domain-specific language clauses and rely on pure-language annotators and methods to introduce workflow operations into existing code.

A number of class-based frameworks have been developed in e-commerce settings, and these tend to provide better support than scientific pipeline frameworks for event-triggered executions, live monitoring, and database operations common to real-time applications. On such framework, Luigi, is similar in spirit to implicit DSLs, but its syntax is implemented as Python classes and methods. Airflow is a pure-python DAG generator – its implementation is closer to a configuration file API than a means to annotate existing code.

Toil is a pure-Python framework developed to take full advantage of cloud infrastructure, featuring a “pluggable backend APIs for machine provisioning, job scheduling and file management” to enable execution on heterogeneous computing environments and sophisticated “caching and streaming” to reduce file system contention (Vivian *et al.*, 2017). Toil received a great deal of attention after a group at UCSF reported it the framework to process an RNA-Seq run of 200,000 samples performed over 90 h on Amazon Web Services, utilizing roughly 32,000 compute cores. The group was able to reduce the cost of analysis by using a combination of Toil optimizations and kmer-based transcript quantification tools. While Toil can ingest CWL, it also includes a number of methods to leverage the Spark-based ADAM toolset developed by the Big Data Genomics (Paten *et al.*, 2015).

Future Directions

Workflows do not exist in a vacuum but are an integral part of the scientific publishing cycle. A major driving factor in workflow standards and innovation has been responding to developments in the cloud, containerization, notebooks, and the semantic web.

The cloud

While the cloud can be considered a rented timeshare of local computing infrastructure, the cloud has introduced many new opportunities for scalability and the sharing of workflows than was previously possible. Several technologies that are relatively rare in academic computing environments have also become de rigueur among workflows, namely object storage. Workflows must accommodate staging files from object store to local volumes. This would be highly impractical without frameworks.

Mixed-use schedulers

Apache Mesos and Apache YARN are cluster management platforms that are designed to conduct job scheduling across distributed heterogeneous networks. While these projects have different origins, they both compete with traditional batch engines such as SGE, LSF, and SLURM.

Cloud-native batch execution engines

Proprietary cloud execution engines such as Microsoft's Azure Batch and Amazon's AWS Batch assume job scheduling and auto-scaling as an integrated feature of the Platform-As-A-Service (PaaS) model. Because they are designed from the ground up to work in the cloud, these engines are equipped to better profile existing CPU, memory, and cost-structures to complete jobs than batch schedulers designed for traditional grids, and they require less setup time. As of this writing Nextflow has already introduced support for AWS Batch, which suggests widespread support for cloud-native engines is likely in the near future.

Serverless computing

Some cloud providers offer a class of services aimed at users who wish to dispense with all of the setup and overhead associated with servers. Serverless platforms such as AWS Lambda, Microsoft Azure Functions, and Google Cloud Functions allow simple code to run without the need to configure and deploy servers. While this "microservices" approach is quite familiar to software developers in e-commerce, rapid adoption in bioinformatics will likely coalesce around specific high-load query cases. Because serverless functions lack the basic process exit status logic of traditional DSL-based frameworks, process status checkpoints need to be manually built to work with file-centric sequence analysis programs.

Dependency management and containerization

The installation and communication of a corpus of versioned compatible tools is a major point of frustration for developers and a concern for reproducible research. Because workflows consist of many tools chained together, the management and harmony of these dependencies is of paramount importance to workflow sharing. Two developments, universal package management and containerization, have addressed this problem using different but potentially compatible approaches.

Universal package management

A package manager that originated from Python, Conda provides an elegant solution by offering a number of dependencies – including Python and R packages and compiled binary executables – in a single versioned requirements file. Conda packages specify other Conda dependencies such as linked libraries, cross-platform binaries that are distributed within the Conda ecosystem through channels. One such channel is Bioconda, which contains over 2700 bioinformatics-specific packages submitted by a wide group of developers and validated using an automated continuous testing and integration scheme.

Containerization

Docker is an open source project that provides a lightweight and configurable operating system virtualization layer called a container. Containers allow software with exact dependencies and requirements to run isolated from the external underlying operating system. This approach ensures software operates consistently and identically on different operating systems, both locally and in the cloud. By isolating programs from each other and the OS, Docker guarantees the replicable execution of scientific software within a workflow regardless of conflicting dependencies or versions with other software in that workflow or software installed by the user (Boettiger, 2015), with no appreciable loss of performance (Di Tommaso *et al.*, 2015).

The Docker architecture utilizes configured scripts called Dockerfiles that are processed to build “images”, ready-to-run files used to instantiate containers. Dockerfiles can themselves be specified with base images, enabling a certain level of templating. The process of building images is far more time consuming than instantiating containers, so it is common to cache these images in a service such as Quay (quay.io). The proliferation of bioinformatics Docker containers has been aided by repositories such as Dockstore (O'Connor *et al.*, 2017) and bioShaDock (Moreews *et al.*, 2015).

In terms of distributing the underlying software behind workflows, dependency management and containers have significant overlap in terms of the goal of providing consistent software across platforms. Conda attempts to do this by providing compiled software and a compatible ecosystem within custom environments. While Conda provides environments and cross-platform dependency management, it does not provide process isolation and depends on a compatible cohort of programs to coexist within an environment, often making exact version specifications impossible. Docker isolates individual programs to eliminate conflict from each other and the underlying operating system. Both approaches are less than ideal for scientific computing, but do provide working solutions, especially when used synergistically. Dockerfiles consist mostly of dependency installation commands and a few exposed ports and paths. Some Docker images use Conda as their primary dependency installation step, and there are now projects, such as Muled, a project within the BioContainers repository (da Veiga Leprevost *et al.*, 2017), that auto-create Docker images based on Conda packages.

The potential for Docker containers to provide a missing technical link in terms of reproducible computational research in bioinformatics has been explored by projects including evaluation of *de novo* assemblers (Belmann *et al.*, 2015). Beaulieu-Jones *et al.* introduced the application of Docker containers using the Drone configuration pipeline engine, allowing the automated evaluation of code changes into the analytical pipeline, which the authors call “continuous analysis” (Beaulieu-Jones and Greene, 2017). While containers can be run in a similar fashion to any command-line software, some pipeline frameworks, such as Nextflow and the CWL-enabled workbenches, offer first-class support for Docker containers.

Containers present an atomic unit of doing work. Docker Swarm and Kubernetes are frameworks that orchestrate hundreds of Docker containers, such as Docker Swarm and Kubernetes, and also offer some level of queueing and resource management, but they compete in a crowded field of existing schedulers.

Workflow sharing

Provided a data set that fits an existing approach, workbenches provide a smooth path for workflow reuse. myExperiment collates workflows from Taverna, Galaxy, and other frameworks into a searchable portal (Goble *et al.*, 2010).

Research Objects aims to bundle the entire stack of data and analysis into a cohesive stack, with a research object bundle (see “Relevant Website” section) and associated workflow ontology (see “Relevant Website” section) which together with a manifest allow researchers to understand an entire analysis from raw data to results (Bechhofer *et al.*, 2010). The motivations and rationale for packaging research objects is described in the highly-cited “Why Linked Data is Not Enough for Scientists” (Bechhofer *et al.*, 2013), which explains why bundling linked data with workflows, results, and publications is preferable to linked data without context.

Notebooks

Notebooks are web-based interactive programming environments. Like Sweave (Leisch, 2002) or knitr (Xie, 2014) literate reports, notebooks support a mix of code and markup, but they are a significant advance in that they allow code to be evaluated in live chunks which retain state. This allows for an easier transition from the type of organic “conversations” typical of analyses in a statistical environment such as R to an automated reproducible report. However, the transition from data preparation steps to pipeline to a notebook is not graceful and currently involves handoffs in the form of intermediate files to store metadata.

The Jupyter notebook is a polyglot derivation of iPython (Perez and Granger, 2007) which supports over 40 languages. The JSON-based .ipynb format recognized by Jupyter been the de facto standard for distributing analyses in the data science community and is gaining acceptance within bioinformatics for rapid dissemination of reproducible analyses (Wang and Ma’ayan, 2016). A static viewer, nbviewer, is available for reading these files in a non-interactive fashion, but few canned solutions exist for instantiating live sessions. A proof of concept demonstrating live notebooks was published in Nature (Shen, 2014) using tmpnb, a Docker-driven temporary notebook engine. An effort from the Freeman neuroscience lab, mybinder.org, accepts Conda requirements files for dependency management and leverages Docker, the Kubernetes container orchestration tool, and Google Cloud Platform to host live repository-driven notebooks.

While they provide an interactive analysis session, notebooks themselves are not integrated development environments (IDEs), and most lack features such as code completion and debugging that IDEs provide. NextflowWorkbench is a project that augments authoring Nextflow pipelines (Kurs *et al.*, 2016) and Dockerfiles using supported JetBrains IDEs.

Although they lack reentrancy frameworks and native support for parallelization, in many ways notebooks are more appropriate for the final steps of analyses than typical workflows frameworks, especially for analysis that rely on statistical tests conducted in

scripting languages or statistical environments. Some notebooks such as Beaker are polyglot – supporting multiple languages simultaneously. Collaborative notebook servers such as CoCalc (previous SageMathCloud), aim to provide live editing for highly collaborative research, but self-hosted collaborative notebooks are still in development. Most cloud workbenches do not yet offer significant support for notebooks and integrating notebooks and workflows is a major area of research (Grüning *et al.*, 2017).

Semantically encoded workflows

Extending semantic encoding to workflows has long been envisioned as a way to make them understandable, discoverable, and more reproducible. For example, semantic encoding may allow researchers to find workflows that use a certain reference data set, a combination of similar tools, or even suggest a biological interaction. All of these scenarios are dependent on semantically encoded linked data. They are also highly dependent on linking data between all the various components and stages of a workflow – input data, tools, pipelines, statistical reports and publication. Fortunately, the theoretical (ontologies) and technical (RDF/OWL) foundations for this endeavor have been established by efforts to create the Semantic Web.

An ontology is a set of terms that provides meaning to data. It builds on controlled vocabularies, by defining formal relationships between concepts. Ontologies have been used extensively to describe biological concepts. Building on ontologies is the concept of linked data, which leverages remote but unambiguous addresses to point to items of data. The combinations of ontologies and linked data forms the theoretical foundation for the semantic web, a set of technologies that allow computers to gain insight into the meaning of data, giving different services an ability to both locate and relate linked data using common web Uniform Resource Identifiers (URIs). The underpinning of the semantic web is the Resource Description Framework (RDF), which allows entities to be related to each other and to attributes using triplets in the form of entity: attribute:value. The relationships themselves are defined by a standard called Web Ontology Language (OWL), in which domain-specific ontologies, including those specific to science, can be expressed.

While RDF and OWL were designed to give computers the ability to transverse the web intelligently, these technologies have been used extensively to describe biological systems in implementations such as Uniprot (Jain *et al.*, 2009), EBI (Jupp *et al.*, 2014), DisGeNet (Queralt-Rosinach *et al.*, 2016), KEGG (Kanehisa and Goto, 2000), Reactome (Joshi-Tope *et al.*, 2005), OpenLifeData (González *et al.*, 2014) and others. A popular compendium of linked biological data resources is Bio2RDF (Callahan *et al.*, 2013).

Linked data can be queried using the SPARQL language. Cytoscape and ChEMBL were early proponents of this strategy. Providing SPARQL endpoints has become especially desirable for complex data such as that hosted by the Cancer Genomics Cloud. Tools such as SADI have been extended to Galaxy to enable complex data queries within workflows (Aranguren *et al.*, 2014). For queries on workflows themselves, Taverna and myExperiment support SPARQL endpoints, as well as the Research Object Hub. This means, in theory, one can use a single query for workflows that rely on certain data, use certain tools, and were published within a certain time period by certain analysts. It is also been posited that semantic representations can be used a high-level standard to translate workflows into other frameworks (Garijo *et al.*, 2014).

A semantic workflow platform, Workflow Instance Generation and Specialization (WINGS) is a project that allows semantically encoded workflows, which are then executed using existing pipeline frameworks (Gil *et al.*, 2011). A key feature of WINGS is the ability to semantically enforce outputs, allowing technical and scientific-based sanity checks to be integrated into workflows.

WINGS is built on existing semantic web standards and workflow-specific ontologies, including PROV, a generic semantic model for describing provenance, consisting of data models (PROV-DM) and ontology (PROV-O) capable of representing typical data lineage (Missier *et al.*, 2013). The Open Provenance Model (OPM) extends PROV for use in workflows. A metadata ontology called Open Provenance Model for Workflows (OPMW) extends OPM, PROV and P-Plan in order to encompass a large range of actors, intents, and concepts. Motivations include the ability to enforce “analytical validity” (Zheng *et al.*, 2015) to encode expert knowledge within workflows.

In configuration frameworks such as workbenches there is a clear distinction between workflow templates and workflow runs, and these are reflected respectively in the ontologies wfdesc and wfprov developed by the wf4ever consortium (Corcho *et al.*, 2012), supported as exports from Taverna via TavernaPROV (Soiland-Reyes, 2016) and CWL-based frameworks, and implemented in Research Objects. CWL itself offers a level of semantic encoding using JSON-LD which should be able to leverage existing ontologies, although existing examples have been mostly focused on file formats.

An important ontology describing the components of workflows is provided by EDAM (Ison *et al.*, 2013), an OWL ontology that can describe a diverse set of tools, datasets, and operations common to bioinformatic workflows. At the analysis level, statistical ontologies such as OBCS (Zheng *et al.*, 2016) may be useful for promoting reproducibility and discovery.

Challenges and Opportunities for Pipelines and Workflows

Unruly provenance

Because workflow performance is highly dependent on both parameters and high-performance computing configurations, this should ideally be encoded into provenance metadata, and some attempts have been made to standardize this in a vendor-agnostic fashion (Santana-Perez *et al.*, 2014). Despite extensive work toward the semantic markup of workflows, simply attaching workflow runs to data may not suffice to provide a transparent provenance for data contained within results. Efforts such as LabelFlow (Alper *et al.*, 2014) and PoeM (Gaignard *et al.*, 2016) aim at providing higher-level context by identifying common usage motifs and combining domain-specific ontologies. Another problem with complex provenance is the crowding of workflow visualizations, making them incomprehensible, suggesting some lightweight annotations are needed to distinguish major and minor steps (Missier *et al.*, 2008). Binding experimental metadata to results is an under-examined step in reproducible computational research, and has been identified as a key element in the sustainability of highly variable data such as metagenomics where sample

preparation and *in silico* choices have a large impact on results (Hoopen *et al.*, 2017). It is possible blockchain technology may also be useful in this area (Neisse *et al.*, 2017).

Workflow decay

The development of large multi-institutional data repositories that characterize “big science” and remote web services that support both remote data usage and the vision of “bringing the tools to the data” make the cloud an appealing replacement for local computing resources (Stein, 2010). This dependence on data and services hosted by others, however, introduces the threat of “workflow decay” (De Roure *et al.*, 2011) that requires extensive provenance tracking to freeze inputs and tools in order to ensure reproducibility at a later date.

Integration of the web

Due to the increase in the size of datasets combined with limitations of networks, web browsers, and web application frameworks, web applications as the main interface for high-throughput analyses have been less than ideal. This prompted Nucleic Acids Research to add a “Stand-Alone Programs for High-Throughput Data Analysis” to their popular web-server issue. However, there is a large gap between pipelines and notebooks, which are the primary tools used by bioinformaticians and GUI-driven interactive analysis which allows researchers to explore data in real-time. The latter has splintered into smaller “single-page” applications, which have been made popular due to easy-to-use web application frameworks such as RShiny which have spawned many convenience utilities (Mattielo *et al.*, 2016; Zhang and Taylor, 2017; Fouillet *et al.*, 2017). The interactive nature of these sites often demand technologies such as AJAX which dispense with the advantages of stable URLs and linked data enjoyed by earlier generations of bioinformatics web applications. Web applications may also disrupt reproducibility by introducing manual and unrecorded steps into an analysis.

Cloud-based workbenches offer some solutions to this problem, because of their scalability and built-in faculties for queues and the ability to spawn runs locally using APIs. But these tools tend to drop off at the point of target file generation, and even report generation and sharing is not a strong suit for workbenches. There is clearly a great deal to be done to bridge the gap from pipelines to open, linked analyses.

A related challenge, in particular for cloud-based commercial workbenches, is providing support for highly customized or interactive web reports as reporting mechanisms. Web-based QC reporting tools such as MultiQC (Ewels *et al.*, 2016) and literature programming outputs such as knitr/R Markdown pose challenges both in terms of security and navigation within hosted infrastructure.

Notebook and Spark integration

Integrating notebooks into a workflow context, so that it can access the workflow and the notebook components can be reused, parameterized, and queried, remains an open challenge. Ideally statistical reports are tied intimately to their respective workflows (i.e., metadata-driven analysis), so changes such as addition of samples are done in one sample table, and these changes are automatically propagated through the pipeline to a notebook or static report. The approach to this propagation differs significantly between DSLs and configuration-based frameworks, the former being more likely to use variables and functions to drive the pipeline and the report. Breaking notebook sessions into file-centric state engines of DSLs, much less the verbose markup of workbenches and other configuration frameworks, completely destroys their powerful interactive and exploratory nature. This approach is precisely the opposite direction of that taken by the Spark community, which intends to bring executable components into distributed data structures that can be used in live notebook sessions. The YesWorkflow project allow developers to use ontology-based lightweight tags to annotate popular scripting languages with provenance metadata (McPhillips *et al.*, 2015). A non-coincidentally named project, noWorkflow, reconstructs provenance through profiling Python code (Murta *et al.*, 2014). These can be used together to generate semi-automated annotations (Belhajjame *et al.*, 2016; Dey *et al.*, 2015). A similar project, Data Narratives (Gil and Garijo, 2017), offers human-readable annotations of workflows.

Apache Spark is a fast, in-memory data processing engine, released as an Scala API but with support for a number of scripting languages. Spark provides a consistent API to perform data analysis without leaving a notebook session and hides many of the inner workings of the distributed memory. The basic abstraction in Spark that allows distributed data to be manipulated as though it were centralized is the Resilient Distributed Dataset (RDD). RDDs themselves implement a DAG to describe changes and provenance, including their dependence on other RDDs. Therefore, Spark itself subsumes some of the functions of pipeline frameworks, provided an entire bioinformatics analysis can be implemented in Spark. Because Spark is not itself a DSL or configured DAG evaluated at runtime, the reentrancy provided by Spark through caching RDDs is not automatic but must be anticipated by the user. Though Spark can certainly behave in concert with workflows – there are extensive example of ADAM in Toil workflows – these are largely still file-centric in nature, using Spark as a distributed replacement for an compiled executable. Spark jobs are deployed on Apache YARN, and this is supported by Cromwell and Toil. However it does not appear there is yet a framework that leverages RDDs as in-memory inputs and outputs, and supports files within the same workflow context.

Limitations of technologies borrowed from elsewhere

Many technologies for bioinformatic pipelines and workflows have been adopted from other areas of scientific computing encompassing the physical and mathematical sciences, but also computer science, data science, information science, e-commerce, finance, and media. As a result, the fit of these tools and infrastructure is often not ideal for bioinformatics. Containers are an excellent example of this phenomenon.

Docker itself offers no dependency management and its approach is often contrary to the natural flow of an analysis – Docker does not enable the easy configured addition of new R packages within an existing environment, for example. Docker was originally designed to address concerns of rapidly deploying e-commerce apps, which rely heavily on databases and web application servers. These web installations do not resemble a typical executable file-transformation pipeline common to scientific computing, and so frameworks for multi-container installations (e.g., Docker Compose) or orchestration (e.g., Kubernetes) are not geared for the start/stop nature of bioinformatic workflows. Docker is also not particularly good at accepting runtime parameters. The Docker daemon requires administrative (either sudo or Docker-group) to run containers, making Docker unfeasible for some shared compute cluster environments (Silver, 2017). A related project developed at Lawrence Berkeley National Laboratory, Singularity, allows more user-centric computing environments composed of many containers to be created and distributed without these administrative privileges.

Continued need for incentives

Despite the interest in semantic encoding from workflow developers, widespread use of semantic markup on workflows remain elusive. There is also no common API for biological file format validation, which would be low-hanging fruit for encouraging semantically defined outputs. Although considerable effort has been put into WINGS, it is built to leverage Pegasus as an execution engine. However, Pegasus is not yet CWL compliant, and the syntax used for semantic enforcement, Apache Jena, is quite verbose. The move toward standardization suggests a good candidate semantic integration moving forward is through the Common Workflow Language.

Almost 3000 workflows are available in myExperiment, although submissions have lagged in the NGS era (only 10 results were obtained for the search term “RNA-Seq”, for instance). It seems likely the introduction of CWL-based workflows will re-energize this repository, but a reinvention of the publishing structure to encourage open workflows as an essential prerequisite to the peer-review process would be a more effective catalyst.

Closing Remarks

Pipelines and workflows are the primary river between scientific data and publications. With the growth of high-throughput data, this river has been made wider by the standardization of workflow languages, deeper by the recognition for the semantic encoding, and is flowing faster thanks to technical advances in cloud computing and containerization. One of the main challenges to future workflow development is keeping the key components of *in silico* scientific processes – data, tools, notebooks – fluid enough to support groundbreaking work and advances from the greater computing community while maintaining standards for reproducible research.

EDITORS IN CHIEF

Shoba Ranganathan holds a Chair in Bioinformatics at Macquarie University since 2004. She has held research and academic positions in India, USA, Singapore and Australia as well as a consultancy in industry. She hosted the Macquarie Node of the ARC Centre of Excellence in Bioinformatics (2008–2013). She was elected the first Australian Board Director of the International Society for Computational Biology (ISCB; 2003–2005); President of Asia-Pacific Bioinformatics Network (2005–2016) and Steering Committee Member (2007–2012) of Bioinformatics Australia. She initiated the Workshops on Education in Bioinformatics (WEB) as an ISMB2001 Special Interest Group meeting and also served as Chair of ICSB's Education Committee. Shoba currently serves as Co-Chair of the Computational Mass Spectrometry (CompMS) initiative of the Human Proteome Organization (HuPO), ISCB and Metabolomics Society and as Board Director, APBioNet Ltd.

Shoba's research addresses several key areas of bioinformatics to understand biological systems using computational approaches. Her group has achieved both experience and expertise in different aspects of computational biology, ranging from metabolites and small molecules to biochemical networks, pathway analysis and computational systems biology. She has authored as well as edited several books as well as articles for the 2013 Encyclopedia of Systems Biology. She is currently an Editor-in-Chief of the Encyclopedia of Bioinformatics and

Computational Biology and the Bioinformatics Section Editor of the Reference Module in Life Science as well as an editorial board member of several bioinformatics journals.

Dr. Gribskov graduated from Oregon State University in 1979 with a Bachelors of Science degree (with Honors) in Biochemistry and Biophysics. He then moved to the University of Wisconsin-Madison for graduate studies focused on the structure and function of the sigma subunit of *E. coli* RNA polymerase, receiving his Ph.D. in 1985. Dr. Gribskov studied X-ray crystallography as an American Cancer Society post-doctoral fellow at UCLA in the laboratory of David Eisenberg, and followed this with both crystallographic and computational studies at the National Cancer Institute. In 1992, Dr. Gribskov moved to the San Diego Supercomputer Center at the University of California, San Diego where he was lead scientist in the area of computational biology and an adjunct associate professor in the department of Biology. From 2003 to 2007, Dr. Gribskov was the president of the International Society for Computational Biology, the largest professional society devoted to bioinformatics and computational biology. In 2004, Dr. Gribskov moved to Purdue University where he holds an appointment as a full professor in the Biological Sciences and Computer Science departments (by courtesy). Dr. Gribskov's interests include genomic and transcriptomic analysis of model and non-model

organisms, the application of pattern recognition and machine learning techniques to biomolecules, the design and implementation of biological databases to support molecular and systems biology, development of methods to study RNA structural patterns, and systems biology studies of human disease.

Kenta Nakai received the PhD degree on the prediction of subcellular localization sites of proteins from Kyoto University in 1992. From 1989, he has worked at Kyoto University, National Institute of Basic Biology, and Osaka University. From 1999 to 2003, he was an Associate Professor at the Human Genome Center, the Institute of Medical Science, the University of Tokyo, Japan. Since 2003, he has been a full Professor at the same institute. His main research interest is to develop computational ways for interpreting biological information, especially that of transcriptional regulation, from genome sequence data. He has published more than 150 papers, some of which have been cited more than 1,000 times.

Christian Schönbach is currently Department Chair and Professor at Department of Biology, School of Science and Technology, Nazarbayev University, Kazakhstan and Visiting Professor at International Research Center for Medical Sciences at Kumamoto University, Japan. He is a bioinformatics practitioner interfacing genetics, immunology and informatics conducting research on major histocompatibility complex, immune responses following virus infection, biomedical knowledge discovery, peroxisomal diseases, and autism spectrum disorder that resulted in more than 80 publications. His previous academic appointments included Professor at Kumamoto University (2016–2017), Nazarbayev University (2013–2016), Kazakhstan, Kyushu Institute of Technology (2009–2013) Japan, Associate Professor at Nanyang Technological University (2006–2009), Singapore, and Team Leader at RIKEN Genomic Sciences Center (2002–2006), Japan. Other prior positions included Principal Investigator at Kent Ridge Digital Labs, Singapore and Research Scientist at Chugai Institute for Molecular Medicine, Inc., Japan. In 2018 he became a member of International Society for Computational Biology (ISCB) Board of Directors. Since 2010 he is serving Asia-Pacific Bioinformatics Network (APBioNet) as Vice-President (Conferences 2010–2016) and President (2016–2018).

VOLUME EDITORS

Mario Cannataro is a Full Professor of Computer Engineering and Bioinformatics at University “Magna Graecia” of Catanzaro, Italy. He is the director of the Data Analytics research center and the chair of the Bioinformatics Laboratory at University “Magna Graecia” of Catanzaro. His current research interests include bioinformatics, medical informatics, data analytics, parallel and distributed computing. He is a Member of the editorial boards of Briefings in Bioinformatics, High-Throughput, Encyclopedia of Bioinformatics and Computational Biology, Encyclopedia of Systems Biology. He was guest editor of several special issues on bioinformatics and he is serving as a program committee member of several conferences. He published three books and more than 200 papers in international journals and conference proceedings. Prof. Cannataro is a Senior Member of IEEE, ACM and BITS, and a member of the Board of Directors for ACM SIGBIO.

Bruno Gaeta is Senior Lecturer and Director of Studies in Bioinformatics in the School of Computer Science and Engineering at UNSW Australia. His research interests cover multiple areas of bioinformatics including gene regulation and protein structure, currently with a focus on the immune system, antibody genes and the generation of antibody diversity. He is a pioneer of bioinformatics education and has trained thousands of biologists and trainee bioinformaticians in the use of computational tools for biological research through courses, workshops as well as a book series. He has worked both in academia and in the bioinformatics industry, and currently coordinates the largest bioinformatics undergraduate program in Australia.

Mohammad Asif Khan, PhD, is an associate professor and the Dean of the School of Data Sciences, as well as the Director of the Centre for Bioinformatics at Perdana University, Malaysia. He is also a visiting scientist at the Department of Pharmacology and Molecular Sciences, Johns Hopkins University School of Medicine (JHUSOM), USA. His research interests are in the area of biological data warehousing and applications of bioinformatics to the study of immune responses, vaccines, inhibitory drugs, venom toxins, and disease biomarkers. He has published in these areas, been involved in the development of several novel bioinformatics methodologies, tools, and specialized databases, and currently has three patent applications granted. He has also led the curriculum development of a Postgraduate Diploma in Bioinformatics programme and an MSc (Bioinformatics) programme at Perdana University. He is an elected ExCo member of the Asia-Pacific Bioinformatics Network (APBioNET) since 2010 and is currently the President of Association for Medical and Bio-Informatics, Singapore (AMBIS). He has donned various important roles in the organization of many local and international bioinformatics conferences, meetings and workshops.

VOLUME 3

Ecosystem Monitoring Through Predictive Modeling <i>Sorayya Malek, Cham Hui, Nanyonga Aziida, Song Cheen, Sooh Toh, and Pozi Milow</i>	1
Large Scale Ecological Modeling With Viruses: A Review <i>Vijayaraghava S Sundararajan</i>	9
Mapping the Environmental Microbiome <i>Lena Takayasu, Wataru Suda, and Masahira Hattori</i>	17
Biological Database Searching <i>Nor A Nor Muhammad</i>	29
Extraction of Immune Epitope Information <i>Guang Lan Zhang, Derin B Keskin, and Lou Chitkushev</i>	39
Characterizing and Functional Assignment of Noncoding RNAs <i>Pradeep Tiwari, Sonal Gupta, Anuj Kumar, Mansi Sharma, Vijayaraghava S Sundararajan, Shanker L Kothari, Sandeep K Mathur, Krishna M Medicherla, Babita Malik, and Prashanth Suravajhala</i>	47
Identification and Extraction of Biomarker Information <i>Vijayaraghava S Sundararajan, Shweta Shrotriya, Monisha Singhal, Pragya Chaturvedi, and Prashanth Suravajhala</i>	60
Computational Systems Biology Applications <i>Ayako Yachie-Kinoshita, Sucheendra K Palaniappan, and Samik Ghosh</i>	66
Coupling Cell Division to Metabolic Pathways Through Transcription <i>Petter Holland, Jens Nielsen, Thierry DGA Mondeel, and Matteo Barberis</i>	74
Studies of Body Systems <i>Amir Feisal Merican, Hoda Mirsafian, Adiratna Mat Ripen, and Saharuddin Bin Mohamad</i>	94
Host-Pathogen Interactions <i>Dean Southwood and Shoba Ranganathan</i>	103
Computational Pipelines and Workflows in Bioinformatics <i>Yosvany López, Piotr J Kamola, Ronesh Sharma, Daichi Shigemizu, Tatsuhiko Tsunoda, and Alok Sharma</i>	113
Constructing Computational Pipelines <i>ChuangKee Ong and Russell S Hamilton</i>	135
Pipeline of High Throughput Sequencing <i>ChuangKee Ong, Qi Bin Kwong, Ai Ling Ong, Huey Ying Heng, and Wai Yee Low</i>	144
Genome Annotation: Perspective From Bacterial Genomes <i>Alan Christoffels and Peter van Heusden</i>	152

Next Generation Sequencing Data Analysis <i>Ranjeev Hari and Suhanya Parthasarathy</i>	157
Exome Sequencing Data Analysis <i>Anita Sathyanarayanan, Srikanth Manda, Mukta Poojary, and Shivashankar H Nagaraj</i>	164
Whole Genome Sequencing Analysis <i>Rui Yin, Chee Keong Kwoh, and Jie Zheng</i>	176
Metagenomic Analysis and its Applications <i>Arpita Ghosh, Aditya Mehta, and Asif M Khan</i>	184
Integrative Analysis of Multi-Omics Data <i>Lokesh P Tripathi, Tsuyoshi Esaki, Mari N Itoh, Yi-An Chen, and Kenji Mizuguchi</i>	194
Profiling the Gut Microbiome: Practice and Potential <i>Toral Manvar and Vijay Lakhujani</i>	200
Functional Enrichment Analysis <i>Srikanth Manda, Daliah Michael, Sudhir Jadhao, and Shivashankar H Nagaraj</i>	218
Prediction of Coding and Non-Coding RNA <i>Ranjeev Hari and Suhanya Parthasarathy</i>	230
Vaccine Target Discovery <i>Li C Chong and Asif M Khan</i>	241
Protocol for Protein Structure Modelling <i>Amara Jabeen, Abidali Mohamedali, and Shoba Ranganathan</i>	252
Structure-Based Drug Design Workflow <i>Ari Hardianto, Muhammad Yusuf, Fei Liu, and Shoba Ranganathan</i>	273
Network-Based Analysis for Biological Discovery <i>Lokesh P Tripathi, Yoichi Murakami, Yi-An Chen, and Kenji Mizuguchi</i>	283
Sequence Analysis <i>Andrey D Prjibelski, Anton I Korobeynikov, and Alla L Lapidus</i>	292
Sequence Composition <i>Bryan T Li, Jin Xing Lim, and Maurice HT Ling</i>	323
Codon Usage <i>Raimi M Redwan, Suhanya Parthasarathy, and Ranjeev Hari</i>	327
Identification of Sequence Patterns, Motifs and Domains <i>Michael Gribskov</i>	332
Epigenetics: Analysis of Cytosine Modifications at Single Base Resolution <i>Malwina Prater and Russell S Hamilton</i>	341
Comparative Epigenomics <i>Yutaka Saito</i>	354
Genetics and Population Analysis <i>Fotis Tsetsos, Petros Drineas, and Peristera Paschou</i>	363
Population Analysis of Pharmacogenetic Polymorphisms <i>Zen H Lu, Nani Azman, Mark IR Petalcorin, Naeem Shafqat, and Lie Chen</i>	379
Detecting and Annotating Rare Variants <i>Jieming Chen, Akdes S Harmanci, and Arif O Harmanci</i>	388

Predicting Non-Synonymous Single Nucleotide Variants Pathogenic Effects in Human Diseases <i>Marwa S Hassan, AA Shaalan, MI Dessouky, Abdelaziz E Abdelnaiem, Dalia A Abdel-Haleem, and Mahmoud ElHefnawi</i>	400
Genome Analysis – Identification of Genes Involved in Host-Pathogen Protein-Protein Interaction Networks <i>Fransiskus Xaverius Ivan, Jie Zheng, Vincent TK Chow, and Chee-Keong Kwoh</i>	410
Comparative Genomics Analysis <i>Hui San Ong</i>	425
Single Nucleotide Polymorphism Typing <i>Srilakshmi Srinivasan and Jyotsna Batra</i>	432
Genome-Wide Haplotype Association Study <i>Yongshuai Jiang and Jing Xu</i>	441
Prediction of Protein-Binding Sites in DNA Sequences <i>Kenta Nakai</i>	447
Genome-Wide Scanning of Gene Expression <i>Sung-J Park</i>	452
Metabolome Analysis <i>Camila Pereira Braga and Jiri Adamec</i>	463
Disease Biomarker Discovery <i>Tiratha R Singh, Ankita Shukla, Bensellak Taoufik, Ahmed Moussa, and Brigitte Vannier</i>	476
Investigating Metabolic Pathways and Networks <i>Md Altaf-Ul-Amin, Zeti-Azura Mohamed-Hussein, and Shigehiko Kanaya</i>	489
Biomolecular Structures: Prediction, Identification and Analyses <i>Prasun Kumar, Swagata Halder, and Manju Bansal</i>	504
Engineering of Supramolecular RNA Structures <i>Effirul I Ramlan and Mohd Firdaus-Raih</i>	535
Predicting RNA-RNA Interactions in Three-Dimensional Structures <i>Hazrina Y Hamdani, Zatil H Yahaya, and Mohd Firdaus-Raih</i>	546
Applications of Ribosomal RNA Sequence and Structure Analysis for Extracting Evolutionary and Functional Insights <i>Chyan Leong Ng and Mohd Firdaus-Raih</i>	554
Computational Design and Experimental Implementation of Synthetic Riboswitches and Riboregulators <i>Munyati Othman, Siuk M Ng, and Mohd Firdaus-Raih</i>	568
Genome-Wide Probing of RNA Structure <i>Xiaojing Huo, Jeremy Ng, Mingchen Tan, and Greg Tucker-Kellogg</i>	574
Assessment of Structure Quality (RNA and Protein) <i>Nicolas Palopoli</i>	586
Study of the Variability of the Native Protein Structure <i>Xusi Han, Woong-Hee Shin, Charles W Christoffer, Genki Terashi, Lyman Monroe, and Daisuke Kihara</i>	606
Identifying Functional Relationships Via the Annotation and Comparison of Three-Dimensional Amino Acid Arrangements in Protein Structures <i>Mohd Firdaus-Raih and Nur Syatila Abdul Ghani</i>	620

Computational Protein Engineering Approaches for Effective Design of New Molecules <i>Jaspreet Kaur Dhanjal, Vidhi Malik, Navaneethan Radhakrishnan, Moolchand Sigar, Anjani Kumari, and Durai Sundar</i>	631
Protein Design <i>Ragothaman M Yennamalli</i>	644
Molecular Dynamics Simulations in Drug Discovery <i>Sy-Bing Choi, Beow Keat Yap, Yee Siew Choong, and Habibah Wahab</i>	652
Protein-Carbohydrate Interactions <i>Adeel Malik, Mohammad H Baig, and Balachandran Manavalan</i>	666
Computational Prediction of Nucleic Acid Binding Residues From Sequence <i>Nur SA Ghani, Shandar Ahmad, and Mohd Firdaus-Raih</i>	678
Protein-Peptide Interactions in Regulatory Events <i>Upadhyayula S Raghavender and Ravindranath S Rathore</i>	688
Homologous Protein Detection <i>Xuefeng Cui and Yaosen Min</i>	697
Mutation Effects on 3D-Structural Reorganization Using HIV-1 Protease as a Case Study <i>Biswa R Meher, Megha Vaishnavi, Venkata SK Mattaparthi, Seema Patel, and Sandeep Kaushik</i>	706
Structural Genomics <i>Shuhaila Mat-Sharani, Doris HX Quay, Chyan L Ng, and Mohd Firdaus-Raih</i>	722
Structure-Based Design of Peptide Inhibitors for Protein Arginine Deiminase Type IV (PAD4) <i>Teo Chian Ying, Zalikha Ibrahim, Mohd Basyaruddin Abd Rahman, and Bimo A Tejo</i>	729
Small Molecule Drug Design <i>Vartika Tomar, Mohit Mazumder, Ramesh Chandra, Jian Yang, and Meena K Sakharkar</i>	741
In Silico Identification of Novel Inhibitors <i>Beow Keat Yap, Chong-Yew Lee, Sy Bing Choi, Ezatul E Kamarulzaman, Maywan Hariono, and Habibah A Wahab</i>	761
Drug Repurposing and Multi-Target Therapies <i>Ammu P Kumar, Minh N Nguyen, and Suryani Lukman</i>	780
Transcriptome Analysis <i>Anuj Srivastava, Joshy George, and Radha KM Karuturi</i>	792
Regulation of Gene Expression <i>Y-h Taguchi</i>	806
Comparative Transcriptomics Analysis <i>Y-h Taguchi</i>	814
Analyzing Transcriptome-Phenotype Correlations <i>Bryan T Li, Jin X Lim, and Maurice HT Ling</i>	819
Transcriptome During Cell Differentiation <i>Dwi A Pujianto</i>	825
Characterization of Transcriptional Activities <i>Adison Wong and Maurice HT Ling</i>	830
Survey of Antisense Transcription <i>Maurice HT Ling</i>	842
Statistical and Probabilistic Approaches to Predict Protein Abundance <i>Rubbiya A Ali, Ali Naqi, Sarah Ali, Mashal Fatima, Musarat Ishaq, and Ahmed M Mehdi</i>	847

Identification of Proteins From Proteomic Analysis <i>Zainab Noor, Abidali Mohamedali, and Shoba Ranganathan</i>	855
Quantification of Proteins From Proteomic Analysis <i>Zainab Noor, Subash Adhikari, Shoba Ranganathan, and Abidali Mohamedali</i>	871
Utilising IPG-IEF to Identify Differentially-Expressed Proteins <i>David I Cantor and Harish R Cheruku</i>	891
Clinical Proteomics <i>Marwenie F Petalcorin, Naeem Shafqat, Zen H Lu, and Mark IR Petalcorin</i>	911
Molecular Mechanisms Responsible for Drug Resistance <i>Mun Fai Loke and Aimi Hanafi</i>	926
Network-Based Analysis of Host-Pathogen Interactions <i>Lokesh P Tripathi, Eiji Morita, Yi-An Chen, and Kenji Mizuguchi</i>	932
Phylogenetic Analysis: Early Evolution of Life <i>Himakshi Sarma, Sushmita Pradhan, Sandeep Kaushik, and Venkata SK Mattaparthi</i>	938
Inference of Horizontal Gene Transfer: Gaining Insights Into Evolution via Lateral Acquisition of Genetic Material <i>Suhaila Sulaiman, Nur S Yusoff, Ng S Mun, Haslina Makmur, and Mohd Firdaus-Raih</i>	953
Gene Duplication and Speciation <i>Tiratha R Singh and Ankush Bansal</i>	965
Epidemiology: A Review <i>Vijayaraghava S Sundararajan</i>	975
Identification of Homologs <i>William R Pearson</i>	980
DNA Barcoding: Bioinformatics Workflows for Beginners <i>John-James Wilson, Kong-Wah Sing, and Narong Jaturas</i>	985
Text Mining Applications <i>Raul Rodriguez-Esteban</i>	996

PREFACE

Bioinformatics and Computational Biology (BCB) combine elements of computer science, information technology, mathematics, statistics, and biotechnology, providing the methodology and *in silico* solutions to mine biological data and processes, for knowledge discovery. In the era of molecular diagnostics, targeted drug design and Big Data for personalized or even precision medicine, computational methods for data analysis are essential for biochemistry, biology, biotechnology, pharmacology, biomedical science, and mathematics and statistics. Bioinformatics and Computational Biology are essential for making sense of the molecular data from many modern high-throughput studies of mice and men, as well as key model organisms and pathogens. This Encyclopedia spans basics to cutting-edge methodologies, authored by leaders in the field, providing an invaluable resource to students as well as scientists, in academia and research institutes as well as biotechnology, biomedical and pharmaceutical industries.

Navigating the maze of confusing and often contradictory jargon combined with a plethora of software tools is often confusing for students and researchers alike. This comprehensive and unique resource provides up-to-date theory and application content to address molecular data analysis requirements, with precise definition of terminology, and lucid explanations by experts.

No single authoritative entity exists in this area, providing a comprehensive definition of the myriad of computer science, information technology, mathematics, statistics, and biotechnology terms used by scientists working in bioinformatics and computational biology. Current books available in this area as well as existing publications address parts of a problem or provide chapters on the topic, essentially addressing practicing bioinformaticists or computational biologists. Newcomers to this area depend on Google searches leading to published literature as well as several textbooks, to collect the relevant information.

Although curricula have been developed for Bioinformatics education for two decades now (Altman, 1998), offering education in bioinformatics continues to remain challenging from the multidisciplinary perspective, and is perhaps an NP-hard problem (Ranganathan, 2005). A minimum Bioinformatics skill set for university graduates has been suggested (Tan *et al.*, 2009). The Bioinformatics section of the Reference Module in Life Sciences (Ranganathan, 2017) commenced by addressing the paucity of a comprehensive reference book, leading to the development of this Encyclopedia. This compilation aims to fill the “gap” for readers with succinct and authoritative descriptions of current and cutting-edge bioinformatics areas, supplemented with the theoretical concepts underpinning these topics.

This Encyclopedia comprises three sections, covering Methods, Topics and Applications. The theoretical methodology underpinning BCB are described in the Methods section, with Topics covering traditional areas such as phylogeny, as well as more recent areas such as translational bioinformatics, cheminformatics and computational systems biology. Additionally, Applications will provide guidance for commonly asked “how to” questions on scientific areas described in the Topics section, using the methodology set out in the Methods section. Throughout this Encyclopedia, we have endeavored to keep the content as lucid as possible, making the text “... as simple as possible, but not simpler,” attributed to Albert Einstein. Comprehensive chapters provide overviews while details are provided by shorter, encyclopedic chapters.

During the planning phase of this Encyclopedia, the encouragement of Elsevier’s Priscilla Braglia and the constructive comments from no less than ten reviewers lead our small preliminary editorial team (Christian Schönbach, Kenta Nakai and myself) to embark on this massive project. We then welcomed one more Editor-in-Chief, Michael Gribskov and three section editors, Mario Cannataro, Bruno Gaeta and Asif Khan, whose toils have results in gathering most of the current content, with all editors reviewing the submissions. Throughout the production phase, we have received invaluable support and guidance as well as milestone reminders from Paula Davies, for which we remain extremely grateful.

Finally we would like to acknowledge all our authors, from around the world, who dedicated their valuable time to share their knowledge and expertise to provide educational guidance for our readers, as well as leave a lasting legacy of their work.

We hope the readers will enjoy this Encyclopedia as much as the editorial team have, in compiling this as an ABC of bioinformatics, suitable for naïve as well as experienced scientists and as an essential reference and invaluable teaching guide for students, post-doctoral scientists, senior scientists, academics in universities and research institutes as well as pharmaceutical, biomedical and biotechnological industries. Nobel laureate Walter Gilbert predicted in 1990 that “In the year 2020 you will be able to go into the drug store, have your DNA sequence read in an hour or so, and given back to you on a compact disk so you can analyze it.” While technology may have already arrived at this milestone, we are confident one of the readers of this Encyclopedia will be ready to extract valuable biological data by computational analysis, resulting in biomedical and therapeutic solutions, using bioinformatics to “measure” health for early diagnosis of “disease.”

Introduction

Water bodies represent significant accumulations of water on the earth's surface. These accumulations of water can include oceans, seas, lakes, ponds and wetlands. They can be still (or contained) or mobile. Rivers, streams, and canals are some examples of natural water. There are also manmade artificial water bodies such as reservoirs and wetlands. In order to maintain aqueous systems capable of sustaining life forms, preserving water quality is very important. However, water bodies all over the world are facing a few common problems, namely eutrophication, sedimentation, and weed infestation. Eutrophication is the result of water bodies' enrichment, increased growth of microscopic floating plants, algae, and the formation of dense mats of floating plants. Algae have long been used to assess environmental conditions in aquatic habitats throughout the world. Algae respond to a wide range of pollutants. They provide an early caution signal of worsening ecological conditions. They are highly sensitive to changes in their environment and therefore a good indicator. Shifts in abundance of algal species can be used to detect environmental changes, and to indicate trophic status and nutrient problems in the lake. Nutrient stimulation of algal growth made algae part of the problem in the eutrophication of lakes, and trophic status of lakes can be monitored by algal taxa found in them (Mogeeb *et al.*, 2012). Chlorophyll-a has been used to estimate algal biomass in aquatic ecosystems as it is common in most algae. Algal biomass indicates the trophic status of a water body. Chlorophyll- a therefore is an effective indicator for monitoring eutrophication, which is a common problem of lakes and reservoirs all over the world (Malek *et al.*, 2011a,b).

Eutrophication can bring the effects of anoxia, which kills fish and invertebrates and results in release of unpleasant and injurious gases. Algae will bloom and other aquatic plants' growth will be uncontrolled. Species and diversity of plants and animals has decreased in number. Polluted water resources can cause severe effects on human as well as aquatic life. Hence, water quality monitoring is essential in exploitation of aquatic resources conservation. Water quality can be defined as a complex of chemical, physical, microbiological, and radiological properties with respect to its suitability for particular purposes (Kambourova, 2006; Boyd, 2015) or simply the physical, chemical, and biological characteristics of water (Orouji *et al.*, 2013). A water quality variable refers to any physical, chemical, or biological property that influences the suitability of water for natural ecological systems or use by humans (Boyd, 2015).

The quality of water helps in regulating the biotic diversity and biomass, energy, and rate of succession. Various factors can affect water quality parameters that are essential in preserving water quality. Quality of water is divided into three main categories, which are physical, chemical, and biological. Physical measurement involves turbidity, color, odor, and taste. Chemical parameters include the organic and inorganic forms of metals and nutrients. Measurement of ammonia nitrogen and iron are used for organic parameters. Meanwhile, inorganic parameters were measured by pH, iron, sulfate, and chloride. The biological parameters include total and fecal coliform, heterotrophic plate count, chlorophyll concentration, and *Escherichia coli* counts (Ngadiman *et al.*, 2016).

Various factors affect water quality parameters. Surface water temperature for example is affected by urbanization and industrial waste that effects fluctuation in dissolved oxygen (DO) concentration in water. DO is important for living organisms in water. The amount of DO in water bodies is dependent on water temperature, sedimentation, amount of oxygen used by respiring and decaying organisms, and amount of oxygen produced from photosynthesizing plants. Water high in organic matter and nutrients can lead to decrease in DO level as a result of increased microbial activity occurring during the degradation of organic matter. Oxygen is an important parameter as it is essential in the metabolism of all aerobic aquatic organisms. Two other important factors are chemical oxygen demand (COD) and biochemical oxygen demand (BOD). COD and BOD are measurements of the susceptibility to oxidation of the organic and inorganic materials and amount of biodegradable organic matter present in water sample. Water pH can be affected by waste or pollutant from human activities. Salinization process leads to reduction on pure drinking water. Turbidity is defined as clarity of water; the clearer the water the higher the water quality. During the raining season turbidity values of water reservoirs are higher due to the sedimentation process. Nutrients such as nitrates, phosphorus, and ammonia are also important for maintaining water quality and aquatic life.

Databases for water bodies contain a vast amount of information that is not possible to be analyzed using conventional statistical methods. Predictive water quality modeling can help to capture relationships among various factors for water quality monitoring. Predictive modeling can be defined as a process by which a model is created or chosen to try to best predict the probability of an outcome (Geisser, 1993). Kuhn and Johnson (2013) modified this definition "to the process of developing a mathematical tool or model that generates an accurate prediction." Studies to develop predictive models for environmental monitoring began by the use statistical approach. A cursory literature search indicates that computational approach to predictive modeling for environmental models is culminated in a volume that was edited by Racknaegel (2003). The computational approach and procedure involve machine learning (ML), a term that literally means learning how to predict from data. ML can be defined as the capability to acquire knowledge by computers without being explicitly programmed. ML algorithms serve as a common tool for data analysis tasks including data imputation, clustering, classification, and regression. However with the

emergence of visualization using Google Earth for water quality monitoring, the investigation and monitoring of water quality has improved. Application of Google Earth gives intuitive visualization and can reflect the relationship between water quality and geographical position. Google Earth Engine enables water resource scientists to overcome tasks involved with remote sensing data analysis such as locating and downloading the data from various providers, data processing, model applications, results interpretation, and accessing current or updated data.

This article presents an overview of ML approaches, followed by application of these methods to water quality modeling, using three representative case studies. Visualization of the results of water quality monitoring is discussed in the final section.

Introduction to Machine Learning Methods in Water Quality Modeling

ML methods are categorized into supervised and unsupervised learning, and optimization techniques. Supervised learning is where a mapping function is used to learn from input variables to an output variable. It is done using a training dataset where the output variable value is already known. The aim of the mapping functions is to adjust the parameters of a particular model such that the outputs of the system approximate the outputs as closely as possible. Supervised learning can be further categorized into classification and regression. Common methods for supervised learning are artificial neural networks (ANN), random forest (RF), and support vector machine (SVM). In unsupervised learning the output variable is not presented during the learning process. The algorithm discovers on its own structures or patterns in data. Unsupervised learning can be categorized into clustering and association. An example for unsupervised learning is Kohonen self organizing feature maps (SOM). Optimization based methods identify the best set of variables that will minimize a predefined cost function. An example includes genetic algorithms (GAs).

Artificial Neural Network

ANNs gather their knowledge by detecting the patterns and relationships in data and learns (or is trained) through experience. An ANN consists of an input layer of neurons (nodes), one or two or even three hidden layers of neurons, and a final layer of output neurons. Each connection is associated with a numeric number called weight ([Wang et al., 2003](#)). [Liu et al. \(2015\)](#) applied decision tree, back propagation neural networks, radial basis neural network, and logistic regression for water quality modeling. The RBF neural network outperformed all three supervised models for water quality prediction with the highest accuracy. [Palani et al. \(2008\)](#) applied an ANN to predict and forecast quantitative characteristics of water bodies such as salinity, temperature, DO, and chlorophyll-alpha. The ANN model was provided with unseen data and was able to simulate values with high accuracy for the desired locations at which measured data are unavailable yet required for water quality models hence making the ANN algorithm a good model when it comes to monitoring of water quality.

Random Forest

[Breiman et al. \(2001\)](#) defined RF, which add an additional layer of randomness to bagging. In addition to constructing each tree using a different bootstrap sample of the data, RFs change how the classification or regression trees are constructed. In standard trees, each node is split using the best split among all variables and is usually not very sensitive to their values ([Liaw and Wiener, 2002](#)). The efficiency, accuracy, and association between trees in the forest improve with increasing number of selected variables. RF model advantages have a high accuracy of classification and variable importance function. The RF model is also nonparametric, does not require data transformation, and is able to handle a large number of predictors ([Cutler et al., 2007](#)). [Hollister et al. \(2015\)](#) applied RF for regression and RF for classification to determine chlorophyll-a concentration and lake trophic status. Both regression and classification models were developed using a combination of in situ and universally available GIS data and only universally available GIS data resulted in higher performance and better accuracy. This indicates that RF can work well for both regression and classification problem. In another study thirteen ML models such as ANN, SVM, RF, K-nearest neighbors, generalized boosted models were compared for the prediction of groundwater dissolved organic nitrogen by [Wang et al. \(2016\)](#). RF was selected as one of the tree based models with optimal model performance illustrating high generalization ability to different data conditions as well as high interpretability. The study identified factors that affect dissolved organic nitrogen using a limited dataset, which can be cost saving in groundwater monitoring. [Yajima and Derot \(2017\)](#) applied a RF model with a sliding window strategy using multivariate historical water quality records of over 10 years to forecast the concentration of chlorophyll-a in fresh and saline water bodies in Japan. The RF model was able to predict trends of the chlorophyll-a in the water bodies with high accuracy and the study concluded that the most dominant parameters for water quality assessment for chlorophyll-a was BOD, COD, pH, and TN/TP.

Support Vector Machine

SVM is a supervised training algorithm that can be useful for the purpose of classification and regression ([Vapnik, 1998](#)). SVM can be used to analyze data for classification and regression using algorithms and kernels in SVM ([Cortes and Vapnik, 1995](#)). Support vector classification (SVC) also is an algorithm that searches for the optimal separating surface. SVC is outlined first for the linearly

separable case (Burbidge and Buxton, 2001). SVM kernel methods are used when complete separations of the two classes are not possible. Some widely used kernels in SVM are polynomial, quadratic, and radial basis function.

Applied SVC and regression (SVR), which was used in monitoring of surface water quality data by predicting biochemical oxygen demand (BOD) of water. The SVR model predicted water BOD values with high correlation value of 0.952, and RMSE of 1.53, hence providing a tool for the prediction of BOD of surface water quality using set of a few measurable variables. Proposed a smooth support vector machine (SSVM) to predict water quality. SSVM is an algorithm that is used for solving nonlinear function estimation problems. The RMSE reported for aquaculture water quality prediction was very low with a value of 0.0275. This value shows that SSVM is proven to be an effective approach to predict aquaculture water quality.

Fuzzy Logic

Fuzzy logic (FL) is an approach to computing based on “degrees of truth” rather than the usual “true or false” (1 or 0) Boolean logic on which the modern computer is based. Fuzzy reasoning is the process in which fuzzy rules are used to transform input into output and consists of four steps: (1) the input variables are fuzzified, (2) the firing strength of each rule is determined, (3) the consequence of each rule is resolved, and (4) the consequences are aggregated. FL rules consist of a premise and consequence and are believed to be able to capture the reasoning of a human working in an environment with uncertainty and imprecision (Shrestha *et al.*, 1996). Used FL to make their complex reservoir optimization models more appealing to operators, who are reluctant to use procedures they do not fully understand. They use optimization techniques, such as deterministic and stochastic dynamic programming. Water quality index (WQI) is determined using a statistical approach and it is used to communicate information on river water quality. Raman *et al.* (2009) used FL method to calculate WQI value and compared the findings with conventional WQI value. The FL base WQI model generated almost similar results with the conventional method. FL is developed using natural language and it is more understandable for river water classification compared to conventional methods and is tolerant towards imprecise data.

Self-Organizing Feature Maps

SOM, also called Kohonen map, is a popular neural network method based on unsupervised learning (Kohonen, 2013). U-matrix is a visualization technique used in SOM. U-matrix visualizes the distances between the neighboring map units and thus portrays the cluster structure of the map. Darker color with the high values denotes the cluster separator while uniform areas of low values indicate clusters (Stefanovic and Kurasova, 2011). In order to extract the most important parameter in assessing high and low flow period variations in terms of river water quality, Sengorur *et al.* (2015) used SOM and ANN to investigate the nonlinear relationship between the input and output variables in complex data for river and water quality management. Chang *et al.* (2008) applied SOM and K-Means arithmetic model on water quality evaluation. An *et al.* (2016) used a combination of principal component analysis (PCA) for dimension reduction and SOM for pattern identification. The author considered that both PCA and SOM are efficient tools to evaluate and analyze the behavior of multivariable, complex, and nonlinear related surface water quality data to unravel patterns, relationship, and the behaviors of water quality parameters used in the study.

Genetic Algorithm

GAs are a type of optimization algorithm, used to find the optimal solution(s) to a given computational problem that maximizes or minimizes a particular function. GAs represent one branch of the field of study called evolutionary computation (Kinnear, 1994) in that they imitate the biological processes of reproduction and natural selection to solve for the “fittest” solutions. GA was applied to determine plant efficiency to reduce wastewater treatment cost in a river basin to improve water quality with high accuracy (Aras *et al.*, 2007). Lee *et al.* (2016) combined GA algorithm with ANN, called a neurogenetic algorithm (NGA). The NGA was designed to determine the effective number of nodes and the optimal activated functions for the ANN structure. NGA and correlation analysis was used to identify input parameters for chlorophyll-a concentrations prediction in lakes used as drinking water sources. The best NGA model architecture was using double hidden layers and logistic sigmoid function that resulted in a high accuracy in training and testing data in comparison to single hidden layer and linear and hyperbolic tangent function.

Case Study: Application of ML Methods in Water Quality Prediction

Common steps involved in water quality analysis are data preprocessing, data splitting model training and testing, and results evaluation. These are the common steps involved in development in almost all ML methods. Finlay (2014) provided steps for building predictive models, which are outlined as follows:

- (1) Exploring the data landscape
- (2) Sampling and shaping the development sample
- (3) Data preparation (data cleaning)
- (4) Creating derived data

- (5) Understanding the data
- (6) Preliminary variable selection (data reduction)
- (7) Preprocessing (data transformation)
- (8) Model construction (modeling)
- (9) Validation

The steps illustrated by Finlay (2014) and Chapman *et al.* (2000) are illustrated in the following case studies for water quality modeling using ML methods.

Case Study 1: Supervised and Unsupervised Method in Water Quality Modeling

Malek *et al.* (2012) applied supervised and unsupervised learning method to identify the relationship between algal abundance with water quality parameters in a tropical lake. The diatom is an algae type that can be used to distinguish water quality status. Two types of ML methods have been applied in this study: Supervised method (Recurrent artificial neural network (RANN)) and unsupervised method (Kohonen self organizing feature maps (SOM)).

RANN is suitable for water quality model prediction involving dynamic time series data. Applied RANN to determine total nitrogen, phosphorus, and DO at Lake Taihu during water diversion. Shim & Tollner applied RANN and sensitivity analysis to predict and identify significant water quality variables at a composting pond. Sensitivity analysis, an analytical approach, was used to select model inputs for RANN. Malek *et al.* (2012) also applied sensitivity analysis where input variables having greater sensitivity value are deemed important and those with smaller values are discarded. Variable selection or dimension reduction is an important step in water quality modeling. This enables effective water quality management by effectively managing limited resources for water quality management. Fig. 1 below illustrates results obtained from sensitivity analysis against output variable, that is, diatom abundance. It can be seen that input variables such as water temperature, pH, DO, and turbidity play an important role in diatom abundance in a lake. RANN model performance in this study was measured using root mean square error (RMSE) and *r* value, which are standard performance evaluators for regression models.

Unsupervised method SOM was applied in this study to classify and cluster diatom abundance using significant variables identified from sensitivity analysis. The SOM generated in this study was confirmed against the sensitivity curve produced from RANN as illustrated in Fig. 2. SOM cluster map and component plane in Fig. 2 illustrates that diatom is highly abundant at lower temperature less than 30° C; this was conformed with results from sensitivity analysis graph.

SOM has also been used for pattern discovery to extract rules governing alga abundance in terms of propositional IF...else rules (Malek *et al.*, 2009, 2010a,b, 2011a,b, 2012). SOM component planes together with SOM cluster map can be used to extract rules to generate a rule-based system prediction.

Case Study 2: Assessment of Predictive Models for Chlorophyll-a Concentration of a Tropical Lake

Malek *et al.* (2011a,b) assesses four predictive water quality models: FL, RANN, hybrid evolutionary algorithm (HEA) and multiple linear regressions (MLR). RANN, FL, and HEA models are suitable for data that represents a nonlinear relationship such as in water quality data. The application of MLR model in water quality modeling in this study was deemed oversimplified as water pollution or eutrophication process represents complex nonlinear relationships between various water quality variables that are not possible to be explained using simplified models.

Fig. 1 Sensitivity analysis graph. Reproduced from Malek, S., Salleh, A., Milow, P., Baba, M.S., Sharifah, S., 2012. Applying artificial neural network theory to exploring diatom abundance at tropical Putrajaya Lake, Malaysia. *Journal of Freshwater Ecology* 27 (2), 211–227. doi:10.1080/02705060.2011.635883.

Fig. 2 SOM showing relationship between diatom density and water temperature.

FL based models on the other hand could provide insight into their own operation because the fuzzy rules provide an easily understood and common sense description of the action of the FL system. FL models have been noted to outperformed feed forward ANN in determining algal concentration and RANN in determining chlorophyll-a concentration (Malek *et al.*, 2010b, 2011a,b).

The study by Malek *et al.* (2011a,b) also uses genetic programming to generate the structure of the rule set and GA for parameter optimization for an HEA based model. The HEA model outperformed FL, RANN, and MLR. In raw datasets, some variables have large variation or spread. Normalization of the raw datasets for predictive modeling approach is an important step to ensure all the variables are within the same range. Variable selection is another important step as presenting a large number of variables to ML algorithms may compromise processing speed. Hence reducing dimension of variables used in model development reduces the size of the ML model architecture, which reduces the processing time, decreases the cost of data collection, and improves accuracy of ML models. Reduction in variable dimension for FL based models provides a simpler formulation of inference rules. In formulating FL membership and inference rules the SOM based approach has been applied by the author. SOM is deemed as an effective approach in formulating FL rules. The preferred method of variable selection should comprise prior knowledge and analytical approaches such as sensitivity analysis, backward elimination, stepwise selection, and genetic algorithm based feature selection.

Model performance evaluation adopted in the study was RMSE, r for regression type of ML models and AUROC for binary classification. RMSE is a measure of the average level of prediction error. It indicates the absolute fit of the model to the data or how close the observed data points are to the model's predicted values. The r value is a measure of correlation between the predicted and observed values of the independent variable. The r value indicates agreement between predicted and observed values but it does not indicate the performance of the models. Models are considered reliable when their predicted values correlate with observed values at r value of 0.5 or above. AUROC curve is a graphical plot of sensitivity or true positive rate versus false positive rate. It is based on binary classification task.

The higher performance of FL model reported by the author over RANN and HEA in this study is due to categorizing continuous response (chlorophyll-a concentration) into two classes. AUROC is a better measure for model evaluation than accuracy, which is measured using RMSE and is suitable for characterizing responses that are dichotomous such as lake eutrophication.

ANN models are "black-box" in nature unlike explanatory methods such as FL and HEA. An FL approach according to the author proves to be a practical and successful technique when dealing with semiquantitative knowledge and semiquantitative data. Generation of membership function and inference rules associated with FL model is dependent on knowledge and expertise of a domain expert, which can be overcome by using the HEA approach, which allows discovery of predictive rule set in complex data. The author noted that there are however drawbacks and advantages associated with each model.

Case Study 3: Support Vector Application

Malek *et al.* (2014) applied SVM for classification to predict categorized values of DO from two freshwater lakes in Malaysia. SVM is a ML method based on statistical theory and derived from instruction risk minimization, which can enhance the generalization ability and minimize the upper limit of generalization error. SVM is able to deal with complex and highly nonlinear data. SVM also works well on a limited dataset and has higher accuracy with better prediction for water quality modeling if a kernel method was used compared to ANN. DO concentration in the study was classified into 3 different category (high, medium, and low) based on guidelines by Department of Environment Malaysia. Classification of output for ML methods should be based on valid and verified categories.

Data preprocessing such as normalization and splitting was carried out to increase efficiency of the model. Data was divided into training and testing datasets. Variable selection method was based on linear SVM kernel in this study. Input parameters were ranked using linear kernel in ascending order based on the cross validation errors. Forward elimination method was then used based on ranked variables for SVM model developed using RBF, ANOVA, and Laplace kernel. Optimum parameters that yield the lowest errors, and highest accuracy were determined. Forward elimination method was used for each SVM model to determine most optimum parameters for water quality modeling. In this study SVM using ANOVA kernel resulted more accurate predication results compared with RBF and Laplacian kernels. The parameters were pH, conductivity, and water temperature. SVM models to predict DO using categorized values of DO yields higher prediction accuracy than using continuous DO value.

Visualization and Google Earth

Visualization is important in investigating and monitoring the quality of water. This is because water quality data collection involves capturing geographic features that allow visualization using maps. Visualization displays the relationship between water quality and geographical position and can aid in effective water quality monitoring.

Malek *et al.* (2015) used visualization and ML algorithm HEA for eutrophication modeling and lake management. The integration of computational data mining using HEA and visualization using thematic maps promises practical solutions and better techniques for eutrophication modeling, especially when datasets have complex relationships without clear distinction between various variables. Thematic maps are considered as an effective method of data visualization and are widely used for coastal management, and detection of the toxic algae and eutrophication. The data visualization approach in this study combines thematic cartography with volume visualization. Volume visualization is a set of techniques that present and show an object without mathematical representation. The study uses a choropleth map, which is a type of thematic map. Choropleth maps represent quantitative data such as percentage, density, and average value of an event in a geographical area using color. The rules generated using HEA are integrated with thematic map visualization over time as depicted in Fig. 3. The

Fig. 3 Illustrates integration thematic map and HEA rules set. Reproduced from Malek, S., Hui, C., Fong, L.C., *et al.*, 2015. Ecological data prediction and visualization system. *Frontiers in Life Science* 8 (4), 387–398. doi:10.1080/21553769.2015.1041167.

Fig. 4 Google Earth for visualization of WQI index. Source: <http://umlivinglabsystem.com>.

visualization system was evaluated by its capability in representing the output data on a map, and by predicting the abundance of chlorophyte based on other water quality parameters. Rules for predicting chlorophyte abundance had a success rate of almost 90%.

The emergence of Google Earth has added a visualization element for water quality monitoring. Google Earth was used for water quality monitoring using climate and hydrology data in South Africa (Silberbauer and Geldenhuys, 2009). Remote sensing via Google Earth is used to evaluate river ecosystem service, which is applicable to any ecoregion and any river size based on the degree of modification and nature (Large and Gilvear, 2014). Assessing water quality on a large scale using remote sensing models can be costly. Applied Google Earth Engine, a petabyte-scale data archive and remote sensing inquiry atmosphere in order to solve the main problems in designing and implementing water quality models on a large scale. Problems related to large amount of data visualization on Google Earth using the heat map was solved using Hadoop, an open source software, to store and process water quality data set effectively for visualization on Google Earth (Huang *et al.*, 2017). In an unpublished study Google Earth application was used to visualize WQI. Visualization of WQI using varying color and shape allows effective communication to the general public regarding water quality status at a particular location. This can assist in decision making for recreational activities as well as water quality monitoring. The WQI index was represented using series of varying color and shapes to indicate water quality status at a particular site as depicted in Fig. 4.

Conclusion

Water quality forecast and management comprises a substantial amount of uncertainty. There are uncertainties involved in water quality measurement methods as well as models used to predict the water quality and actions required to maintain the water quality status. These models however are necessary to assist water quality personnel involved in monitoring and managing water quality as deteriorating quality of natural water resources such as lakes, streams, and estuaries is a problem faced by mankind. Therefore, monitoring and effectively managing water resources is vital in order to optimize the quality of water. The problems associated with water contamination can be handled if water quality is predicted early using predictive models. This concern has been addressed in many prior studies, however, extensive work is still required in terms of applicability, efficiency, and reliability of existing water quality modeling. The methods presented here can be applied to other ecosystems, in order to sustain a healthy environment.

Large Scale Ecological Modeling With Viruses: A Review

Vijayaraghava S Sundararajan, Ministry of Environmental Agency, Singapore; Bioclues.org, Hyderabad, India

© 2019 Elsevier Inc. All rights reserved.

Introduction

Ecology is the study of organisms and their environments. Viruses are not usually categorized as free living organisms and merely treated as part of the environment. From late 1980s, several researchers started validating through molecular, experimental, micrographic, and model-based research on how viruses should be considered as ecological actors, and it was established that viruses are regulators of planetary biogeochemistry. A study by OMalley (2016) suggests that viruses should be considered as ecological actors that are comparably equal to organismal actors (OMalley, 2016).

In this review article, we will describe previous research studies in modeling large scale data with Dengue virus, in and around Singapore. These research methodologies, statistical analysis, and steps will give researchers an idea in how to deal with the large scale virus data and create models on virus locally and internationally to take appropriate steps to prevent the diseases spread.

1. Dengue viruses (DENV) cause 500,000 infections (dengue hemorrhagic fever, DHF, shock syndrome, and DSS) (WHO, 2009). DENV is a single stranded positive sense RNA virus with an 11.8 kb genome flanked by two untranslated regions, a single coding region, the precursor of membrane (prM), and seven nonstructural proteins (Chambers *et al.*, 1990). Being a RNA virus, DENV undergoes a rapid evolutionary process (Holmes and Burch, 2000; Holmes and Twiddy, 2003) and selects strains with enhanced adaptation, resulting in mutant variants that differ in their ability to spread and cause disease (Holmes and Burch, 2000; Twiddy *et al.*, 2002) and all four DENV serotypes are capable of causing severe dengue clinically (Whitehorn and Simmons, 2011). Previous studies implicated host genetics (Coffey *et al.*, 2009; Khor *et al.*, 2011) immune response (Green and Rothman, 2006), infection status, and viremia levels (Wang *et al.*, 2006; Vaughn *et al.*, 2000) as predisposing factors for severe dengue. Mild to severe dengue outbreaks subsequent to emergence of a DENV-2 genotype of Asian origin in Latin and Central America (Rico-Hesse *et al.*, 1997a) were seen and disease severity could be even strain-dependent (Holmes and Burch, 2000). Viral genetic differences correlate with clinical severity (Pandey and Igarashi, 2000; Tuiskunen *et al.*, 2011; Chen *et al.*, 2008; Leitmeyer *et al.*, 1999; Guzman *et al.*, 1995) and virus attenuation (Whitehead *et al.*, 2003) to support the strain-dependent concept of virulence.
2. Dengue reemergence is increasingly associated with a shift in epidemiology to older cohorts with different clinical manifestations and severity compared with very young children (Chen and Vasilakis, 2011). The dengue serotypes circulating all year round in Singapore are DENV-1, DENV-2, and DENV-3 with sporadic reports of DENV-4 (Lee *et al.*, 2010). There were major outbreaks in 2005 by DENV-1 and by DENV-2 in 2007 (Ler *et al.*, 2011). DENV-1 and DENV-2 are the main circulating serotypes out of 4 types (Ministry of Health, 2012). Infections with different serotypes may cause nearly identical clinical syndrome (Halstead, 2008), but some differences in clinical manifestations have been reported, although conclusions are usually based on limited serotype comparisons and small sample sizes (Chan *et al.*, 2009; Kumaria, 2009). The exception is a recent large cross-sectional study from the Americas comprising 1716 children and adults (Halsey *et al.*, 2012). Multiple factors have been suggested to contribute to severe dengue (SD) such as secondary infections, age, viral load, as well infecting serotype and genotype (Burke *et al.*, 1988; Guzman and Kouri, 2003; Rico-Hesse *et al.*, 1997b; Sangkawibha *et al.*, 1984). Infection with secondary DENV-2 is more likely to result in severe disease compared with other serotypes (Balmaseda *et al.*, 2006; Fried *et al.*, 2010; Nisalak *et al.*, 2003; Vaughn *et al.*, 2000). Primary DENV-1 cases were more overt whereas primary DENV-2 and DENV-3 cases were usually silent (Guzman *et al.*, 2012, 2000). DENV-2 genotype in is the Asian genotype rather than the Cosmopolitan genotype circulating in Singapore (Rabaa *et al.*, 2010; Zhang *et al.*, 2006) and extensive diversity resulting in epidemic potential (Rico-Hesse, 2003).
3. The “United in Tackling Epidemic Dengue (UNITEDengue)” portal was launched on August 28, 2012, to initiate cross-border dengue case and virus surveillance (Ng, 2011). In Singapore, the economic impact of dengue during 2000–2009 was estimated about US\$1.15 billion (Carrasco *et al.*, 2011) and in Klang Valley, Malaysia during 2005–2009 is about US\$56 million (Shepard *et al.*, 2012; Suaya *et al.*, 2009). In 2013, Malaysia reported a total of 43,348 cases (peak in 2008 with 49,335) and Singapore reported a historical high of 22,170 cases (Anon, 2013; Anon, 2014a), which was almost 50% more than the worst dengue epidemic in 2005 with 14,209 cases, over previous years (2008–2012).
4. In the Western Pacific Region (such as, ...), dengue is the main viral infection that occurs yearly in multiple countries due to complex interplay of virus, vector, and host biology, as well as climatic and socioeconomic factors (Arima *et al.*, 2015; Bhatt *et al.*, 2013; Lee *et al.*, 2012; Ritchie, 2014; Banu *et al.*, 2011; Wilder-Smith and Gubler, 2008). A 2014 study showed that DENV-serotype switches from previous years (Governments of Malaysia and Singapore, 2014; Anon, 2014b) and secondary heterotypic infection is believed because larger numbers equal severe dengue cases (Guzman *et al.*, 2013). External quality assessment (EQA) is used to compare laboratory performance and reveal potential problems associated with diagnostic kits or procedures (Anon, 2011a). The WHO Regional Office for the Western Pacific launched an EQA for dengue diagnostics testing in 2013, under the Asia Pacific Strategy for Emerging Diseases (APSED) 2010 (Anon, 2012a).
5. *Aedes aegypti* vectors acquire the dengue virus when they feed on viremia hosts (the dengue infected human patient) (Kramer and Ebel, 2003) and the role of mosquito vector in the transmission of dengue fever was first recognized by Bancroft (1906). In 1906, feeding

mosquitoes on dengue patients was further studied by Cleland *et al.*, (1919, 1918). Comprehensive human to mosquito transmission studies were conducted in the Philippines (Siler *et al.*, 1926; Simmons *et al.*, 1931), and several epidemiologically important observations (Nguyet *et al.*, 2013) in Vietnam involve feeding mosquitoes with vertebrate blood spiked with cell cultured virus, using a device, such as a “double-jacketed” glass cylinder (Rutledge *et al.*, 1964) or a Hemotek membrane feeding system (Diehlmann, 1999). Earlier studies may not accurately mimic that of the natural setting (Rodhain and Rosen, 1997) and infection rates were lower in mosquitoes (Jupp, 1976; Meyer *et al.*, 1983), and use of virus stock that had been frozen and thawed, or phenotypic virus adaptation due to numerous passages in cell culture (Richards *et al.*, 2007; Chen *et al.*, 2003; Miller, 1987).

6. In the Western Pacific Region during the 2014 outbreaks, there were 1513 dengue cases in the Solomon Islands (Anon, 2014c) 45,171 cases in China, and 108,698 cases in Malaysia (Anon, 2015), and Japan reported its first autochthonous outbreak in over 70 years (Arima *et al.*, 2014; Kutsuna *et al.*, 2015). DENV-serotype 3 was found to be circulating in the Pacific after an absence of 18 years (Cao-Lormeau *et al.*, 2014). CHIKV has probably had an unappreciated circulation in the region due to its cocirculation with DENV (Weaver and Lecuit, 2015; Horwood *et al.*, 2013). Zika virus, a flavivirus that was detected in Asia in the 1960s but has recently emerged in the Pacific and the Americas (Kindhauser *et al.*, 2016), is linked to clusters of microcephaly and other neurological disorders that WHO declared on 1-Feb-2016 as of international concern (Anon, 2016). *A. aegypti* and *A. albopictus* mosquito vectors require different control strategies (Yap *et al.*, 2010) and clinicians require specialized training to treat severe dengue cases (Anon, 2012b). Genotype data is useful for tracking the movement of viruses and for risk assessment (Hapuarachchi *et al.*, 2016), and point-of-care tests for dengue diagnosis (Prat *et al.*, 2014) was introduced. EQA in the WHO Western Pacific Region (Pok *et al.*, 2015b) was studied and APSED (Anon, 2011b) was initiated.

Research Studies

Clinical Outcome and Genetic Differences Within a Monophyletic Dengue Virus Type 2 Population (Hapuarachchi *et al.*, 2015)

The new findings showed that primary and secondary infections that progressed to DHF and DSS were likely due to host rather than virus factors.

Data: DENV-2 with 89 whole genomes were obtained from patients diagnosed with dengue fever (DF, $n=58$), dengue hemorrhagic fever (DHF, $n=30$) and dengue shock syndrome (DSS, $n=1$) during July 2010 to January 2013 in Singapore. 70% of DENV-2 serotyped cases in Singapore (2007–2011) (Han *et al.*, 2012) were noted. Primary and secondary infection cases (Gan *et al.*, 2014) were based on serum IgM and IgG in patient sera, by using Panbio Dengue Capture IgM ELISA and Dengue Capture IgG, and Indirect IgG ELISA kits.

Method: Viral RNA was extracted from patient sera/plasma by using the QIAamp Viral RNA Mini Kit and crossing point values from the real-time PCR assay results were used as a surrogate indicator of virus titers (Lai *et al.*, 2007). DENV was isolated from sera/plasma using the *Ae. albopictus* clone C6/36 mosquito cell line (ATCC CRL-1660). The presence of DENV in cell supernatants was confirmed by an immunofluorescent assay (IFA) using DENV group-specific and serotype-specific monoclonal antibodies derived from hybridoma cultures (ATCC: HB112, HB114, HB47, HB46, HB49, and HB48).

Packages: Contiguous sequences were assembled using the Lasergene package version 8.0 and were aligned in the BioEdit Sequence Alignment Editor version 7.0.9.0 (Hall, 1999). The phylogeny of study sequences was inferred by the maximum likelihood (ML) method based on the general time reversible substitution model and gamma distributed rates with invariant sites in MEGA 6.06 (Tamura *et al.*, 2013). The median joining network was constructed using the whole genome sequences in Network version 4.6.1.2 (Bandelt *et al.*, 1999). Genome-wide dN/dS ratios were computed using Hyphy package (Pond *et al.*, 2005). The single likelihood ancestor counting, fixed effects likelihood, internal fixed effects likelihood, and the mixed effect model of evolution methods (Murrell *et al.*, 2012) were used to detect the molecular signatures of selection within an alignment of 272 complete coding sequences (Asian, American Asian, and American genotypes of DENV-2) consisting of all study isolates ($n=89$) and those obtained from the GenBank database. Significance levels were set at $p<0.05$ and the secondary structures of the variable region of 3' UTR and complete 5' UTR of wild type (NS2A-V83) and mutant (NS2A-V83I) variants of DENV-2 cosmopolitan clade III were predicted using the mfold web server under standard conditions (37°C) (Zuker, 2003). The statistical significance, using R software (RCoreTeam, 2013) on association of primary and secondary infections within the DHF and DSS categories was calculated using the exact binomial test. Probability values less than 0.05 were considered statistically significant.

Conclusions: 89 patients were modeled as DF=58 and DHF=30, DSS=1. 45 patients had secondary dengue infections and 27 patients had primary infections and the primary/secondary status of 17 patients could not be classified. Findings indicated that subtle genetic differences in a highly homogenous, monotypic DENV-2 population potentially modified the clinical outcome of study subjects, regardless of primary and secondary infection status.

Dengue Serotype-Specific Differences in Clinical Manifestation, Laboratory Parameters, and Risk of Severe Disease in Adults, Singapore (Yung *et al.*, 2015)

Serotype-specific features and disease severity on patients from April 2005 to December 2011 were studied on dengue hemorrhagic fever (DHF) and severe dengue (SD). 469 dengue-confirmed patients comprising 22.0% dengue virus serotype 1 (DENV-1), 57.1% DENV-2, 17.1% DENV-3, and 3.8% DENV-4 were studied.

Patients: The study included dengue cohorts recruited from two service settings: Primary care clinics and Singapore's Communicable Disease Centre, an infectious disease center that provides an outpatient walk-in service supporting Tan Tock Seng Hospital, a university teaching hospital with 1500 beds.

Methods: Phylogenetic analysis on DENV sequences was conducted by using the maximum-likelihood method as implemented in PAUP* software and compared with sequence data obtained from GenBank. Serology testing was carried out using: Platelia™ NS1 ELISA, Panbio® Dengue IgG Indirect, IgG Capture, and IgM Capture ELISAs.

Data: Headache, drowsiness, eye pain, muscle pain, joint pain, rash, bleeding, anorexia, nausea, vomiting, red eyes (conjunctival injection), and abdominal pain are used as clinical manifestations in the analysis. The WHO (2009) warning signs of lethargy/drowsiness, severe abdominal pain, and mucosal bleeding were assessed as one variable defined as patients who fulfilled any of the three warning signs (WS). Plasma viral RNA level, temperature, systolic blood pressure, pulse rate, hematocrit, platelet, and leukocyte count at the first day of presentation were analyzed. Between April 2005 and December 2011, a total of 3468 patients were enrolled into study cohorts.

Analysis: For descriptive analyses, number and percentage were used for categorical variables; median and range were used for continuous variables. The χ^2 test was used to compare univariate categorical data whereas Fisher's exact test was used if expected cell sizes <5. Adjustment was done for clinically relevant potential confounders: Age, gender, year of infection, recruitment site, fever day, and primary/secondary infection status unless stated otherwise. All analysis was done using R and in-house SAS software.

Results: Dengue was confirmed in 617 (18.2%) patients. Serotype information was available for 469 (76%) of dengue-confirmed patients comprising 103 (22.0%) DENV-1, 268 (57.1%) DENV-2, 80 (17.1%) DENV-3, and 18 (3.8%) DENV-4.

Conclusion: DENV-1 infection may be more severe compared with DENV-2 infection. A findings model that included a prospective adult dengue cohort found that DENV-1 cases were more likely to present with red eyes whereas absence of red eyes but presence of joint pain and lower platelet count was associated with DENV-2 cases. The differences in severity may be attributable to variations in plasma viral RNA levels between serotypes. At a molecular level, our findings may be associated with DENV-1 genotype 1 and DENV-2 cosmopolitan genotype.

Dengue Outbreaks in Singapore and Malaysia Caused by Different Viral Strains (Ng *et al.*, 2013)

A consortium of ASEAN countries formulated UNITEDengue with 14,079 circulating DENV in a cross-border surveillance program revealed that in the 2013 outbreaks in Singapore and Malaysia, the predominant virus in Singapore switched from DENV2 to DENV1, with DENV2 becoming predominant in neighboring Malaysia. Dominance of DENV2 was most evident in the southern states where higher fatality rates were observed. A shared secured web-portal UNITEDengue (see "Relevant Website section") features weekly incidence, monthly Dengue virus (DENV), serotype distribution, and sequences of the envelope (E) gene of viruses.

DENV serotype surveillance revealed that outbreaks in both countries were associated with a switch in predominant serotypes. In Malaysia, DENV2 overtook a preexisting DENV3 and DENV4 dominance pattern in 2013 (Fig. 1(A) and (B)). DENV2 was most dominant in the southernmost states of Johor and Malacca (Fig. 1(C)), where the proportion of DENV2 rose to 70%–90% after August 2013. Incidentally, the fatality rates of 0.5% in those two states were unusually high when compared with those of the whole of Malaysia and Selangor (0.18% and 0.08%, respectively), where surveillance protocols were the same. The association of DENV2 dominance with high fatality is of concern although the reasons remain unclear. Hypothetically, it could be because of the inherent virulence of DENV2 strain or the antibody-dependent enhancement, which causes sequential infection of DENV1 (or DENV3) followed by DENV2 to be more severe.

Envelope gene-based virus surveillance: DENV1 strains circulating in Singapore during the 2013 epidemic were first detected in November 2012 and belonged to genotype III. From April 2013 onward, more than 50% of all viruses sampled in Singapore clustered in this clade. Interestingly, only 42 (12%) of 349 DENV1 samples sequenced in Malaysia belonged to this clade. The predominant DENV2 strain found in Johor and Malacca belonged to the cosmopolitan genotype (named as cladeIb) and was distinct from those that were predominant in the northern part of Malaysia. Though closely related to the cosmopolitan virus that caused Singapore's outbreak in 2007, and to strains that continue to circulate in Singapore, DENV-2 cladeIb in Johor and Malacca clustered distinctively (supported by a bootstrap value of 98%) from DENV-2 strains in Singapore. Out of five dengue-related death cases in Johor, four were due to cladeIb viruses. Close monitoring in Singapore initially detected sporadic cases (40 (11%) out of 363 DENV2 sequenced) due to cladeIb, and seven of those 40 sequences were identical to the cladeIb strains in Johor. Incidentally, the first death case in Singapore in early 2014 was due to a virus from the same clade.

First Round of External Quality Assessment of Dengue Diagnostics in the World Health Organization Western Pacific Region, 2013 (Pok *et al.*, 2015a)

Nineteen national-level public health laboratories from 18 countries and areas (two in Vietnam) in the WHO Western Pacific Region where dengue is endemic or where imported cases have been detected were invited to participate in the EQA. All 19 agreed and the EQA panel was dispatched to these laboratories between May and July 2013, and the labs performed routine dengue diagnostic assays on a proficiency testing panel consisting of two modules.

Fig. 1 (A) Monthly distribution of DENV serotypes in Singapore 2012–2014. (B) Monthly distribution of DENV serotypes in Malaysia 2012–2013. Predominant serotype switched from DENV2 to DENV1 in Singapore, while it switched from DENV3/4 to DENV2 in Malaysia. (C) Spatial distribution of predominant DENV serotypes in Malaysia and Singapore (2013). Reproduced from Ng, L.-C., Chem, Y.-K., Koo, C., *et al.*, 2013. Dengue outbreaks in Singapore and Malaysia caused by different viral strains. *American Journal of Tropical Medicine and Hygiene* 92, 1150–1155.

Module A: Samples A2013-V01 and A2013-V03 contained at least 10^6 RNA copies/mL of in vitro-cultured DENV of different serotypes: DENV-1 genotype III and DENV-2 cosmopolitan clade II, deposited in Genbank with accession numbers KP685233 and KP685236, respectively.

Module B: Samples B2013-S01 and B2013-S02 were split serum samples from a convalescent dengue patient included to assess reproducibility of testing by the participating laboratories. These samples were confirmed by PRNT to contain neutralizing antibodies against DENV 1–4 ($> 1:1000$) and confirmed DENV-negative.

Analysis: In Module A, two points each were awarded for the correct detection of DENV by RT-PCR or NS1 assay and accurate serotyping of DENV. In Module B, two points each were awarded for the correct detection of anti-DENV IgG and IgM antibodies. The final score was the proportion of points earned out of the possible awardable points. Accuracy for each assay (e.g., serotyping) was defined as the proportion of laboratories scoring 100% for that assay. Quantitative data (RT-PCR cycle threshold values and ELISA values) submitted were used for reference and for assessing reproducibility of laboratory results. For ELISA assays, the percentage coefficient of variation was calculated from values recorded in triplicate runs to evaluate the reproducibility of results.

Module A: (Viral RNA and NS1 antigen): For laboratories using RT-PCR in Module A, the majority (11/16) used the QIAmp Viral RNA Mini Kit for extraction and purification of DENV RNA and commercial kits to perform RT-PCR. More than half (56.3%) used real-time RT-PCR, while the remainder used conventional RT-PCR methods. The laboratory reporting equivocal results for the negative sample in Module A used the real-time methodology.

Module B: (Serology): All 18 laboratories that requested Module B chose the ELISA methodology to detect anti-DENV IgM. Half used the Panbio Dengue IgM Capture ELISA with two also using a rapid diagnostic test. The two laboratories detecting anti-DENV IgM in only one of the split samples used an in-house IgM MAC-ELISA protocol and a commercial Dengue IgM ELISA kit, respectively. This first round of EQA in the Western Pacific Region strengthens the regional public health laboratory system for detecting emerging infectious diseases, in line with APSED (2010).

Results: Module A was performed by 16 laboratories with reverse transcriptase polymerase chain reaction (RT-PCR) for both RNA and serotype detection. Of these, 15 had correct results for RNA detection and all 16 correctly serotyped the viruses. All nine laboratories performing NS1 antigen detection obtained the correct results. Sixteen of the 18 laboratories using IgM assays in Module B obtained the correct results as did the 13 laboratories that performed IgG assays.

Membrane Feeding of Dengue Patient's Blood as a Substitute for Direct Skin Feeding in Studying Aedes-Dengue Virus Interaction (Tan *et al.*, 2016)

Understanding the interaction between Aedes vectors and DENV has significant implications in determining the transmission dynamics of dengue. The absence of an animal model and ethical concerns regarding direct feeding of mosquitoes on patients has resulted in most infection studies using blood meals spiked with laboratory-cultured DENV.

Patients: The patient criteria were: (1) Adult, ≥ 21 years of age, (2) ≤ 5 days of fever, and (3) positive for DENV by point-of-care dengue NS1 Ag rapid test kit (Standard Diagnostic Inc., Korea) and written consent was obtained. A total of 26 dengue patients, 20 (80%) were found to be infected with DENV-1, three (12%) were infected with DENV-3, and two (8%) with DENV-2. The viremia level (DENV Log₁₀ RNA copies/ml) of patients ranged from 4.75 to 9.41 (DENV-1), 3.73 to 5.6 (DENV-2), and 3.69 to 8.69 (DENV-3).

Methods: The number of RNA copies in patient's serum was measured using a TaqMan® one-step qRT-PCR assay targeting a highly conserved 3'UTR region of DENVs. Oligonucleotide sequences used were DENVF2: 5'-AAACAGCATATTGACGCTGGGA-3' and DENVR3: 5'-GGCGYTCTGTGCTGGAATGATG-3', with a probe sequence of 5'-FAM-AGACCAGAGATCCTGCTGTCTC-MGB-3'. PCR reactions were carried out using the TaqMan® Fast Virus 1-step Master Mix. Larvae were reared in 25 cm $\times$ 30 cm $\times$ 9 cm enamel pans containing 800 mL of water and fed with Plecomin® fish food (Tetra, Germany). Pupae were placed in 30 cm $\times$ 30 cm $\times$ 30 cm (H $\times$ W $\times$ L) cages. 17–34 mosquitoes (4–6 days old) were transferred into paper cups covered with net and were starved for at least 24 h before exposure to dengue patients. After the EDTA blood was collected, the cup was placed on patient's forearm and the mosquitoes were exposed to feed through the net for 15 min. Total RNA was amplified from mosquito midguts using the QIAamp Viral Mini. The number of RNA copies in mosquito midguts was estimated using the same TaqMan® one-step qRT-PCR assay.

Feeding rates: Overall, DSFA consistently resulted in higher mosquito feeding rates when compared to membrane feeding. In 11 out of 25 feeding events, a significantly higher number of mosquitoes were found to be fully engorged when they fed directly on a patient's arm as compared to those fed on the EDTA blood through a membrane ($P \leq 0.05$). Direct skin feeding consistently achieved more than 90% feeding rates, while the rates for membrane feeding were between 48.2% and 98.2%.

Results: Direct skin feeding assay (DSFA) consistently showed higher mosquito feeding rates (93.3%–100%) when compared with the membrane feeding assay (MFA) (48%–98.2%). Pair-wise comparison between methods showed no significant difference in midgut infection rates between mosquitoes exposed via each method and a strong correlation was observed in midgut infection rates for both feeding methods ($r = 0.89$, $P < 0.0001$). A strong correlation between salivary gland infection and patient serum viremia were observed for both DSFA ($r = 0.80$, $P < 0.0001$) and MFA ($r = 0.79$, $P < 0.0001$) methods. Unlike midgut infection, salivary gland infection was only observed in mosquitoes that fed on patients with viremia of more than 5.5 Log₁₀copies/ml.

External Quality Assessment of Dengue and Chikungunya Diagnostics in the Asia Pacific Region, 2015 (Soh *et al.*, 2016)

Twenty-four national-level public health laboratories performed routine diagnostic assays on a proficiency testing panel consisting of two modules. Module A contained serum samples spiked with cultured DENV or chikungunya virus for the detection of nucleic acid and DENV nonstructural protein 1 (NS1) antigen. Module B contained human serum samples for the detection of anti-DENV antibodies.

Analysis: The appropriate dengue diagnostic tools must be used at the correct time for the correct diagnosis of dengue. While 19/24 (79.2%) laboratories employed assays for both acute (RT-PCR) and recent (anti-DENV IgM) DENV infection, four performed antibody testing for dengue but lacked assays for early detection (preantibody immunological response) of dengue such as RT-PCR or NS1 kits and one could perform RT-PCR but had no serology capacity. With an incomplete set of diagnostics, these laboratories may be unable to diagnose a proportion of DENV infections and should consider quickly strengthening their capacity through the use of commercial ELISA assays for the detection of NS1 antigen or anti-DENV IgM antibodies. Accuracy was high ($\geq 85\%$) for DENV and CHIKV detection and DENV serotyping by RT-PCR. The few errors in DENV detection (false negatives) appeared to be clustered in samples A2015-V01 and V02, which were identical, high-titer DENV-1 samples. Most of the inaccuracies in Module A were in NS1 testing. Specifically, 87.5% of NS1 testing errors were derived from a single DENV-positive sample, A2015-V03, being reported as negative or equivocal (7/8 laboratories), particularly when using the Platelia Dengue NS1 Ag kit. This suggests that the NS1 levels in the sample may have been at the threshold of detection for the kit, making complementary assays for virus detection, such as RT-PCR, highly relevant.

RESULTS: Among 20 laboratories testing Module A, 17 (85%) correctly detected DENV RNA by reverse transcription polymerase chain reaction (RT-PCR), 18 (90%) correctly determined serotype, and 19 (95%) correctly identified CHIKV by RT-PCR. Ten of 15 (66.7%) laboratories performing NS1 antigen assays obtained the correct results. In Module B, 18/23 (78.3%) and 20/20 (100%) of laboratories, correctly detected anti-DENV IgM and IgG, respectively. Detection of acute/recent DENV infection by both molecular (RT-PCR) and serological methods (IgM) was available in 19/24 (79.2%) participating laboratories.

Introduction

On the earth, highly diverse bacteria adaptively reside in various environments from animal and plant body sites to extreme environments such as the deep ocean and hot springs. The total number of bacterial cells on the earth are estimated to be $4\text{--}6 \times 10^{30}$, suggesting that the total amount of cellular carbon from bacteria exceeds that of plants and animals (Whitman *et al.*, 1998). Bacteria inhabiting natural environments such as oceans, fresh water, and soil play important roles in global resource renewal cycles such as the carbon cycle and nitrogen cycle by making organics and inorganics available to other living things. On the other hand, animal- and plant-related microbiomes are highly dense compared with environmental microbiomes (Whitman *et al.*, 1998), although total cell numbers are less than those of environmental microbiomes (Table 1). Among them, human-associated microbiomes are attracting attention in the medical field, as current studies strongly suggest the profound relationship between the human gut microbiome and host health and disease.

The human microbiomes such as the gut, oral, and skin microbiome are known to be highly body-site-specific and highly variable between individuals (The Human Microbiome Project Consortium, 2012). These characteristic features of human microbiomes are associated with various internal and external factors such as host genetic background, dietary intake, antibiotic use, pregnancy, age, and geography (Benson *et al.*, 2010; Wu *et al.*, 2011; Manichanh *et al.*, 2010; DiGiulio *et al.*, 2015; Yatsunenkov *et al.*, 2012; Goodrich *et al.*, 2014). In addition, microbial imbalance, called dysbiosis, was also observed in patients with various diseases such as inflammatory bowel disease (IBD), type 2 diabetes, and obesity (Frank *et al.*, 2007; Qin *et al.*, 2012; Karlsson *et al.*, 2013; Turnbaugh *et al.*, 2009), demonstrating that the structural change in normal microbiomes is linked with diseases and the host homeostasis. Furthermore, in 2013, fecal microbiota transplantation (FMT), in which feces from healthy donors are transplanted to disease-afflicted patients, was first reported to be an effective therapy for chronic colitis caused by *Clostridium difficile*, and since then FMT has been tried for various diseases (Van Nood *et al.*, 2013; Moayyedi *et al.*, 2015). These studies implied that the human gut microbiome is involved in both disease onset and health maintenance. In fact, it was reported that some human gut species regulate differentiation and proliferation of pro- and antiinflammatory T cells (Treg and Th17) in the gut (Atarashi *et al.*, 2013, 2015). However, since the microbial community is composed of numerous species that interact with each other and with host cells with complex mechanisms, elucidating the feature of bacterial community through time and space is required to exactly and deeply understand how the microbial ecosystem is shaped and how it maintains our health by controlling the microbiomes.

Background/Fundamentals

In the 1800s, knowledge on bacterial fermentation and infectious diseases accumulated for the agricultural and medical fields by development of methods for isolating and culturing the bacterial species from the natural environments and host animals/humans. Today, the technologies for DNA analysis have revolutionarily advanced, enabling us to comprehensively evaluate ecological and functional features of the microbial communities and ecosystems, which is represented by a culture-independent metagenomic sequencing of the microbial community using next-generation sequencing (NGS) technologies. We herein present the development and improvement of analytical methods in microbiome research.

Table 1 Order of bacterial cell number on the earth

	Location	Order of Bacterial cell number
Environment	Soil	$10^{29}\text{--}10^{30}$
	Fresh water	10^{26}
	Sea water	10^{29}
Host-related	Human	10^{23}
	Animal	10^{24}
	Plant	10^{26}

Culture-Based Approach

Pure culture technology by which the specific microbial species are isolated and cultured on agar was established in the 1800s by Pasteur and Koch and others, and since then, microbiologists have intensively performed culture-based studies of pathogenic bacteria causative for human infectious diseases, and microorganisms useful for fermentation such as wine production in agriculture. In 1885, the commensal bacterium *Escherichia coli* was isolated from human feces by Theodor Escherich, and the early anaerobic culturing method succeeded in the pure culture of *Bifidobacterium* in 1899. In the mid-1980s, culture-independent DNA-based technologies such as bacterial 16S ribosomal RNA (rRNA) gene analysis were developed, and revealed that many more bacteria existed in environments including the human gut than those isolated by the conventional cultural methods. For example, only about 0.1% of bacteria in the ocean and 0.3% in the soil could be cultivated (Amann *et al.*, 1995). Thus, naturally occurring microbes include many species difficult to culture in the laboratory (Staley and Konopka, 1985).

DNA-Based Approach

In 1978, Carl Woese proposed three domains of life (bacteria, archaea, and eukaryotes) based on ribosomal RNA genes of which the gene products RNA molecules are essential components of ribosome in the cell. In the microbial ecological study, the 16S rRNA gene sequence has been extensively used to be a molecular marker in the taxonomy of prokaryotes (Woese and Fox, 1977; Woese, 1987). The first culture-independent 16S rRNA gene analysis of the environmental microbiome was reported in 1990 (Giovannoni *et al.*, 1990). The paper showed that the bacterial diversity estimated by the 16S gene data far exceeded that by the culture-dependent approach.

Another incredible advance in the culture-independent approach is use of the NGS technologies in place of the traditional Sanger method-based sequencing coupled with the recombinant DNA technology, which began around 2005, leading to the high-throughput analysis of 16S rRNA gene sequences from community samples with low cost. The NGS technologies have also determined numerous 16S rRNA gene and genome sequences of tens of thousands of microbes isolated individually, of which the databases are useful for precise assignment of the observed 16S sequences to known bacterial taxa by sequence similarity search, establishing a solid way to elucidate the overall microbial community structure.

However, it is difficult for the 16S rRNA gene analysis to obtain or infer the community's functional features such as metabolism of various biological compounds. To uncover the functionality of the microbial community, the metagenomic analysis based on whole genome shotgun sequencing was developed as the third method, in which many of the microbial gene sequences in the community can be randomly and comprehensively determined (Venter *et al.*, 2004; Tyson *et al.*, 2004). For the human gut microbiome, metagenomic sequencing was performed by the traditional Sanger method in the early days (Gill *et al.*, 2006; Kurokawa *et al.*, 2007), and thereafter by NGS technologies in 2009 and 2010 (Turnbaugh *et al.*, 2009; Qin *et al.*, 2010). Gene sequences can be assigned to the function by similarity search to public databases such as KEGG (Kyoto Encyclopedia of Genes and Genomes) and COG (Clusters of Orthologous Groups) (Kanehisa *et al.*, 2002; Tatusov *et al.*, 1997). In addition, the NCBI genome database composed of numbers of the individual microbial genome sequences has also been developed (see "Relevant Website section"). Particularly, the genome database of human-derived cultured microbes allowed us to analyze not only the gene composition but also the taxonomic composition in human microbiomes by directly mapping metagenomic sequences to the microbial genomes.

Application

We herein showed two popular methods using 16S rRNA gene and metagenomic sequences produced by NGS for human microbiome research.

16S rRNA Gene Analysis

The 16S rRNA gene (16S) analysis may be used most frequently for investigating the microbial diversity and composition in microbial communities coupled with the subsequent computational analysis of 16S sequences. The 16S rRNA gene is about 1500 bp long and contains conserved regions (functionally important) and nine alternatively located variable regions (V1–V9; functionally less important) among bacterial species (Andersson *et al.*, 2008; Fig. 1). The sequence similarity or diversity in variable regions can be used to discriminate taxonomically different species and to identify the particular species. In the 16S analysis, DNA fragments containing variable regions of almost all bacterial species in the community are simultaneously amplified by universal PCR primer sets annealed to the conserved regions.

The overall process of typical 16S analysis using the MiSeq sequencing system was shown in Fig. 1. MiSeq is the NGS that produces reads of ~350-bp covering at least two variable regions (e.g., V1–V2 in Fig. 1) by paired-end sequencing. Since MiSeq and other NGS sequencers generate tens of millions of 16S reads with one sequencing run, it is possible to sequence 16S amplicons from multiple different samples simultaneously in one sequencing run by using different sets of barcoded universal primers for the samples. The 16S reads of several thousands to ten thousands per sample are then subjected to quality check to remove low-quality reads including ones less than threshold of the average quality value (QV < 20) of base-calling, lacking PCR

Fig. 1 Outline flowchart of 16S rRNA gene analysis.

primer sequences, and possible chimerisms. After trimming PCR primer sequences from the filter-passed reads, high-quality reads are clustered with a 97% sequence identity to obtain taxonomically different groups called operational taxonomic units (OTUs), which correspond to the bacterial “species.” The number of observed OTUs represents the community’s species richness (called α diversity), the number of 16S reads in an OTU approximates the abundance of the OTU, and their ratio represents the relative composition of all the OTUs. It is noted that overestimation of the OTU number is generally observed in the clustering of NGS reads with the sequencing error rate as high as $\sim 0.5\%$. Therefore, clustering of more 16S reads with the high error rate generates OTUs greater than the actual species number (Kim *et al.*, 2013). The bacterial taxa are assigned for the OTUs by similarity search of the OTU-representative 16S reads to the public 16S databases (Ribosomal Database Project (Cole *et al.*, 2008) and Green genes (DeSantis *et al.*, 2006)) and the NCBI genome database (also see below). Several software programs such as QIIME are useful for 16S analysis (Caporaso *et al.*, 2010). Direct mapping of all the 16S reads to the 16S and genome databases without making OTUs can also be used to analyze the species diversity and richness in the microbial community (Miyake *et al.*, 2015).

For evaluation of the overall structural similarity between two or more bacterial communities (called β diversity), the UniFrac distance analysis was developed for the 16S data (Lozupone and Knight, 2005). In this analysis, the similarity of phylogenetic trees constructed from the OTU sequences between the communities is calculated as UniFrac distance based on the common branch length between the samples. The UniFrac distance ranging from 0 to 1 represents 100% and 0% similarity between the communities. Furthermore, principle coordinate analysis (PCoA) based on UniFrac distance is also a useful tool to visualize the overall structural similarity between the samples (also see below). Multivariate analysis such as permutational multivariate analysis of variance (PERMANOVA) is used to test the statistical significance of the similarity and dissimilarity between different communities.

Metagenomic Analysis

As described above, the 16S analysis provides the microbial profiles in the communities, but it is not suitable to obtain functional features of the communities. On the other hand, metagenomic sequencing can collect many gene sequences representing the function of microbial communities.

The process of metagenomic analysis is shown in Fig. 2. Microbial DNA prepared from the community is subjected to whole-genome shotgun sequencing by NGS. Tens of millions of metagenomic reads of ~ 300 bp accounting for a total of several gigabases per sample are obtained and filtered with the quality check to remove low-quality reads similar to the 16S analysis. There are two processes for microbial and functional profiling in the metagenomic analysis. For the functional analysis, metagenomic reads are assembled with appropriate assemblers such as Newbler to obtain nonredundant microbial sequences/contigs, from which protein-coding genes can be predicted by several prediction software programs such as MetaGeneAnnotator (Noguchi *et al.*, 2008). The predicted genes are then subjected to similarity search to functional databases of genes and metabolic pathways such as COG and KEGG to assign and classify the genes into functions. The quantification of the identified genes is performed by mapping metagenomic reads to the genes. For the microbial analysis, taxonomic assignment and quantification of the microbial abundance

Fig. 2 Outline flowchart of metagenomic analysis.

can be conducted by mapping metagenomic reads to the NCBI genome databases compiled with more than 20,000 individual genomes including ~3000 human microbes. Metagenomic analysis usually requires a high-spec computation system to handle larger datasets than the 16S analysis. For the high-performance computational analysis, cloud server systems such as MG-RAST have been developed, in which the quality check and calculation of the community's structures regarding microbial and functional profiles can be carried out automatically (Meyer *et al.*, 2008).

Most of metagenomic sequencing analyses have used NGS sequencers such as Illumina HiSeq and MiSeq because those rapidly collect large amounts of sequence data with low cost. However, since these sequencers produce short reads of ~300 bp, and the assembly of them generates relatively short contigs possibly containing misassembled contigs mainly due to the presence of high-similarity sequences such as 16S rRNA genes and horizontally transferred genes within and between microbial genomes in the community. Therefore, short-read assembly includes some ambiguity in reconstruction of individual genomes and contigs. To improve these problems encountered in standard short-read sequencing, several computational tools have been developed for reconstruction of the high-quality genomes by binning short contigs based on coabundance across samples (Nielsen *et al.*, 2014; Alneberg *et al.*, 2014; Kang *et al.*, 2015; Cleary *et al.*, 2015), and by incorporating independently preassembled synthetic reads of ~10 kb in assembly of short reads, which improved the assembly accuracy and the contig length (Sharon *et al.*, 2015; Kuleshov *et al.*, 2016). Use of long-read NGS sequencers such as PacBio and MinION that produce longer reads (>10 kb) than the short-read sequencers is also an alternative approach to improve the outcomes in metagenomic analysis (Leonard *et al.*, 2014; Tsai *et al.*, 2016). Actually, long-read sequencing facilitated accurately assembled long contigs for a wide range of individual microbial and eukaryotic genomes (Rasko *et al.*, 2011; Chin *et al.*, 2013; Chaisson *et al.*, 2015).

Illustrative Example(s) or Case Studies

Diversity Index

There are several indices to evaluate ecological profiles of the microbial community structure. The simplest diversity index is the number of distinct OTUs/species detected in 16S analysis and the number of genomes mapped by metagenomic reads in metagenomic analysis (see section “Application”). In 16S analysis, unseen novel species can be included as unassigned OTUs that have <70% identity with known species, while only known species/genomes having high similarity to metagenomic reads are identified but original genomes/species of unmapped reads are still unknown in metagenomic analysis. Also, estimation of the microbial abundance may be more or less influenced by the PCR bias at the amplification step of the target 16S rRNA gene using universal primers in 16S analysis, while metagenomic analysis includes no PCR step at all. These differences may cause some discrepancy in the outcomes between these two methods. Other diversity indices, Chao1 and ACE, are also used for estimating the maximum OTU/species number by extrapolation of the observed OTU number, respectively (Chao, 1987; Chazdon *et al.*, 1998).

The Shannon index is also a popular metric for evaluation of the community structure, in which both the species richness and the abundance evenness are considered. The Shannon index is calculated based on Shannon’s information entropy, that is, the more equally distributed the microbial abundance, the higher the score of the index when the species richness is the same.

We compared the OTU (see section “16S rRNA Gene Analysis”) number, the Shannon index, and the number of phyla based on our in-house 16S datasets among 39 microbiomes including 23 gut microbiomes of orangutans (domestic zoos), humans (Japanese healthy adults), pigs (domestic farms), experimental mice (conventional), and experimental rats (conventional); foliar microbiomes of *Cerasus* and *Ginkgo*, and four soil microbiomes from a potato field; and five samples from river fresh water (Saitama, Japan) and five samples from oceanic water (Saga, Japan) (Fig. 3). The soil communities showed the highest diversity in the three indices followed by the sea and river communities. The diversity in the sea communities was slightly higher than that of river in all three indices. The three indices also revealed the tendency of the diversity to be relatively lower in the host-related microbiomes than the environmental microbiomes, suggesting less complex community structure of the host-related microbiomes than the environmental ones. These differences also suggest that the host-related microbiomes have selective pressures on the colonization by host physiology including immunity compared with the environmental microbiomes.

Cumulative Relative Abundance Distribution

We observed the cumulative relative abundance distribution (CRAD) shared among various types of human gut microbiomes from healthy adults, infants, and disease-afflicted patients where the taxonomic composition was significantly varied (Takayasu *et al.*, 2017b). The CRADs showed linear relationship between the population size of bacterial species (X) and the existing bacterial species number holding more than X in a log-log plot, which can be approximated by power law function.

CRADs of the 39 microbiomes described above also indicated the linearity in a log-log plot (Fig. 4), suggesting that all of the microbial communities from environments, animal guts, and plants also follow the power law. However, the slopes of the CRADs corresponding to the power exponent of power law function were distinct ranging from 0.6 and 1.5 among the microbiomes, in which the soil community was characterized by the highest power exponent, and the human microbiome by the smallest power exponent. These data suggested that the exponent of CRAD has the tendency of correlation with the α diversity indices represented by the species richness and the Shannon index.

Taxonomic Assignment

We showed the average phylum-level microbial composition of 10 communities from the different hosts and environments described in 4.1 based on 16S data in Fig. 5, respectively. The species assignment of the 16S OTUs was performed with similarity search with a 70% identity to the databases. The soil community was dominated by higher number of phyla than the others, as

Fig. 3 Comparison of diversity indices of various microbiomes.

Fig. 4 Cumulative relative abundance distributions of various microbiomes.

Fig. 5 The average bacterial composition of nine microbiomes based on 16S data. (A) Nine microbiomes at the phylum level. (B) Nine microbiomes at the genus level.

shown in Fig. 3. The environmental microbiomes were prominently dominated by the species belonging to the phylum Proteobacteria, while the host-related microbiomes were dominated by the species in Firmicutes. Four major phyla, Proteobacteria, Bacteroidetes, Actinobacteria, and Firmicutes occupied up to ~92% of the total abundance in all microbiomes except for soil, for which the combined abundance of the top four phyla (Proteobacteria, Actinobacteria, Chloroflexi, and Acidobacteria) was around ~76% of the total abundance. Several phyla such as Gemmatimonadetes and Nitrospirae were characteristically detected in the soil microbiomes. The hydrosphere microbiomes (river and sea) were abundant in two phyla, Proteobacteria and Bacteroidetes, different from the leaf and soil microbiomes. On the other hand, the animal gut microbiomes were dominated by the four phyla, Firmicutes, Bacteroidetes, Actinobacteria, and Proteobacteria up to 99% or more with the strong selective pressure on the colonization as described above.

However, at the genus-level species assignment, many of the microbiomes were composed of many of the unidentified species distinct from known genera, particularly for orangutans, mice, rats, soil, and sea (Fig. 5(B)). This poor genus-level assignment may be largely due to an insufficient number of bacterial strains isolated from these environments and the high abundance of phylogenetically distant species from known species in these communities. Thus, taxonomic analysis based on the 16S and metagenomic data largely depends on the quality of the databases, although the overall structural or functional features can be evaluated from these data. In contrast, the database of human microbes has been systematically constructed by an effort of the Human Microbiome Project for the current 10 years, in which genomes of ~3000 human microbes were determined. Similarity search of human microbiome 16S data to the public 16S and genome databases was performed with the range from 97% to 70% identities. Almost all of the OTUs can be assigned to known phyla with a $\geq 70\%$ identity, 60% of them to genera with a $\geq 94\%$ identity, and 30% of them to species with a $\geq 97\%$ identity, while less than 20% of murine gut OTUs can be assigned to known genera and species (Fig. 6(A)). The combined abundance of the assigned OTUs in the human gut microbiome accounted for over 80% of the total abundance at the genus and species levels, indicating that the majority of dominant species in the human gut microbiome were uncovered and the species yet-unidentified might be minor members (Fig. 6(B)). The sufficient taxonomic assignment of pig microbiomes may be because the highly abundant species were coincidentally shared between human and pig microbiomes. Again, poor species assignment of mouse, rat, and orangutan microbiomes at the genus level may be due to insufficient 16S and genome databases and phylogenetic differences in the constituted taxa between gut microbiomes of these animals and humans, similar to the environmental microbiomes mentioned above. For taxonomic assignment in metagenome analysis, metagenomic reads are directly mapped to known genomes in the genome databases with a $\geq 95\%$ identity and a $\geq 90\%$ length coverage. The reads mapped to known genomes account for ~70% of the total reads in human gut microbiomes (Nishijima *et al.*, 2016).

Fig. 6 Taxonomic assignment of 16S data of human and mouse gut microbiomes. (A) Ratios of OTUs taxonomically assigned at the species, genus, and phylum levels. (B) Ratios of 16S reads taxonomically assigned at the species, genus, and phylum levels.

Multivariate Analysis Based on Unifrac Distance

We herein show three examples of multivariate analysis based on the Unifrac distance calculated from 16S data. The Unifrac distance-based PCoA of the nine microbiome samples is shown in Fig. 7(A). The results revealed that the gut samples from the same hosts tended to aggregate to make independent clusters both in the weighted and unweighted Unifrac distance analyses, respectively, in which clusters of the human, orangutan, and pig gut samples were close to each other, but distant from those of the rodent (mouse and rat) gut samples, which were close to each other in the unweighted Unifrac analysis. All of the four environmental samples clearly form a cluster distinct from the gut samples both in the weighted and unweighted Unifrac analyses. The unweighted Unifrac distance analysis considers the presence or absence of the phylogenetically close OTUs/species between the samples, while the weighted Unifrac distance considers differences in the abundance of commonly existing OTUs/species between the samples (Lozupone and Knight, 2005). The present data suggested that the human, orangutan, and pig gut microbiomes were relatively similar to each other in the species members compared with the rodent gut microbiomes, both of which had similar species members. The human and orangutan

Fig. 7 Unifrac distance-based PCoA of various microbiomes. (A) Weighted and unweighted Unifrac distance-based PCoA of nine microbiomes (orangutans, humans, pigs, mice, rats, leaves, soil, river water, and oceanic water). (B) Weighted and unweighted Unifrac distance-based PCoA of human microbiomes from feces, saliva, gastric juice, plaque, skin (cheek), and skin (forearm). (C) Weighted and unweighted Unifrac distance-based PCoA of human salivary microbiomes from IBD patients and healthy subjects.

gut microbiomes also had relatively similar species abundance, but differed from the pig gut microbiomes in the species abundance. Similarly, although the mouse and rat gut microbiomes had relatively similar species members, the species abundance was different between them. The four environmental microbiomes had relatively similar species members and abundance compared with the different gut microbiomes. In addition, the high similarity between the human and orangutan microbiome structures suggested that the host's genetics more or less contributed to shaping of the gut microbiomes (Goodrich *et al.*, 2014).

We also showed an example for the UniFrac-based PCoA of human microbiomes from different body sites including gut, saliva, plaque, gastric juice, and two skins (cheek and forearm) in Fig. 7(B). The results revealed that the gut samples formed a distinct cluster from the other samples both in the weighted and unweighted UniFrac distance. The saliva, plaque, and gastric juice samples tended to form clusters relatively similar to each other, suggesting that the two oral microbiomes had relatively close community structure with the gastric microbiomes (Tsuda *et al.*, 2015). The two skin samples also formed a distinct cluster from each other though the inter-individual diversities were relatively high comparing to non-skin samples.

Fig. 7(C) further shows an example for the UniFrac-based PCoA analysis of the salivary microbiomes between healthy individuals and patients with IBD. The results found that both samples were segregated from each other both in the weighted and unweighted UniFrac analyses, indicating the typical dysbiosis of the IBD salivary microbiomes (Said *et al.*, 2013). The differences between the two sample sets showed the statistical significance with P -values < 0.01 by Student's t -test.

Periodic Analysis

Several studies have reported the long and short-term periodic changes in the microbial composition of host-related and environmental microbiomes (Kuipers *et al.*, 2000; Thaïss *et al.*, 2014; Takayasu *et al.*, 2017a). A few computational tools have been developed to determine the diurnal periodicity of the microbial abundance in the gut and salivary microbiomes across samples longitudinally collected at time intervals (Hughes *et al.*, 2010; Takayasu *et al.*, 2017a). We herein introduce a method called the periodicity discrimination method (PDM), which uses the Fisher exact test, and can be effective even for small datasets often containing the "zero read" abundance across the samples (Takayasu *et al.*, 2017a). In the PDM, the time series abundance data of each day were first subjected to the min-max normalization, respectively, and the average normalized abundance of each time zone was calculated. Next, the time zones of a day were divided into two groups, and the Fisher exact test p -value was calculated for every combination of the two groups for every possible relative abundance threshold.

We showed diurnal changes in the human salivary microbiome as an example using the PDM. We obtained 16S data from the salivary samples collected from six healthy adults with 4-h intervals for three consecutive days. The periodicity of species abundance in longitudinally collected samples for each individual was evaluated by the PDM. The results revealed that the higher abundant genera tended to have the stronger circadian periodicity, and the genera accounting for 68.4%–89.6% of the total abundance significantly oscillated (Fig. 8(A)). The two major phyla, Bacteroidetes and Firmicutes, were found to have the periodicity of ~ 24 h by auto-correlation coefficient analysis (Fig. 8(B)). The analysis also revealed that the two highly abundant genera *Prevotella* and *Streptococcus* had the opposite oscillation patterns in which the abundance of *Prevotella* increased exclusively in the morning, while that of *Streptococcus* increased exclusively in the evening in the all six subjects, respectively (Fig. 8(C)). We further showed the oscillated patterns in the gene functions of the salivary microbiomes by metagenomic analysis (Fig. 8(D)). The functions of salivary microbiomes were categorized by assigning the metagenomic genes to functions in the KEGG database. The results showed that the circadian oscillation appeared to enrich the functions of environmental responses such as various transporters and two-component regulatory systems in the evening, and those of metabolisms such as the biosynthesis of vitamins and fatty acids in the morning.

Discussion

We presented several analytical methods and tools useful for evaluation of the 16S and metagenomic data of various types of microbiomes. The analysis of a community's diversity suggested the strong selective pressure of host physiologies on the colonization of host-related microbiomes compared with the environmental microbiomes. The taxonomic analysis revealed differences in the dominant species between host-related and environmental microbiomes at the phylum level, and poor species assignment at the genus level for many of the environmental microbiomes. Multivariate analysis based on the UniFrac distance showed that the microbiomes were highly variable according to their habitats in the host-related and the environmental microbiomes. Significant differences in the overall community structure of the salivary microbiome between the IBD patients and healthy individuals suggested the profound association between the salivary microbiome and the host's physiological state. The response of the salivary microbiome to the host's signals may also be the case for the circadian oscillation of the human salivary microbiome, implying the concerted regulation of the human microbiome with the host's homeostasis.

As described above, various microbiomes exhibited similar CRADs, which follow the power-law-like long-tail distribution, and the power exponents are likely to be characteristic to the animal and environmental microbiomes, respectively. The power-law-like long-tailed cumulative distribution is distinct from the Gaussian distribution generally observed in stature and manufacturing quality distributions. In the economic sciences, it has been reported that the richest, accounting for 20% of the world's population, contribute to $\sim 80\%$ of the world's total income (United Nations Development Program, 1992; Table 3.1). Interestingly, this distribution in human society structure is analogous to the CRADs representing the microbial community structure where a small numbers of species predominate the abundance in the community over a vast number of other members. For example, $\sim 20\%$ of the species contribute to 80%–90% of the total abundance in the adult human gut microbiomes as shown in Figs. 3–5. It is of

interest to explore whether there is a similar mechanism for development and establishment of the community structure between human society and gut microbial community.

We also proposed a mathematical model for the power-law-like CRADs in the microbial communities, in which the observed CRADs were reproduced by incorporation of a parameter of spatial competition for the nutrient source between bacterial species (Takayasu *et al.*, 2017b). When the bacteria in the compact assemblage like biofilm or particulate organic matters compete with each other for common nutrient sources, the species with higher proliferation rate could access more resources than other groups with lower rates, resulting in a long-tail structure with large differences in the abundance between these species after repeating the spatial competition. This simple mathematical mechanism could produce power law CRADs similar to those observed in many of the gut microbiomes.

Future Directions

In the environmental microbiomes, it is anticipated to manipulate and improve the environment by controlling bacterial community, which is deeply associated with resource renewal cycles, while the host-related microbiomes are expected to be keys for developing therapies for diseases. Practically, FMT showed the feasibility of medical treatments for several diseases such as *Clostridium difficile* associated diarrhea, irritable bowel syndrome, and acute graft-versus-host disease (Van Nood *et al.*, 2013; Mizuno *et al.*, 2017; Kakihana *et al.*, 2016). However, since mechanisms for successful FMT have been largely unknown, it will be required to explore how donor microbiomes change and shape the alternative form contributing to healing in the patient gut. Our mathematical model for proliferation and restoration of the human gut microbiome will be useful for these FMT studies.

In addition, microbiomes may also be potential biomarkers that respond to changes in host physiologies. This is because the human salivary microbiome is sensitive to systemic changes in a host's physiological states such as circadian rhythms and lesions in the IBD gut as shown here, but likely to show little sensitivity to external stimuli such as dietary intake and administration of medicines including antibiotics (Cabral *et al.*, 2017). The human salivary microbiome was also reported to be a potential marker for pancreatic cancer, which is difficult to diagnose in the early stage (Farrell *et al.*, 2011).

Closing Remarks

OTU number, the Shannon index, and the observed phylum number are shown for five gut microbiomes from orangutans (domestic zoos), humans (Japanese healthy adults), pigs (domestic farms), experimental mice (conventional), and experimental

rats (conventional), foliar microbiomes of *Cerasus* and *Ginkgo*, and three natural environmental microbiomes from soil (a potato field), river fresh water (Saitama, Japan), and oceanic water (Saga, Japan). The data are obtained from 16S data.

CRADs of nine microbiomes indicated in Fig. 3 are shown. The sample numbers are five for orangutans, five for humans, five for pigs, three for mice, five for rats, one for leaf *Cerasus*, one for leaf *Ginkgo*, four for soil, five for river fresh water, and five for oceanic water, respectively. The exponents (β s) of CRADs calculated from the given equation are shown.

Nine microbiomes are from feces of orangutans, humans, pigs, mice, and rats, and from leaves, soil, river water, and oceanic water, respectively.

Biological Database Searching

Introduction

Biological databases are databases which store information from biological experiments, especially high throughput molecular experiments. There are many types of biological databases, including sequence databases, protein domain databases, protein structure databases, and non-coding RNA databases, among others. These databases house biological information that can be used for annotation and characterization of new biological data. New inferences may also be obtained from processing data from these databases using bioinformatics.

A simple analysis pipeline that uses biological databases would consist of four main steps (Fig. 1). First would be the data collection step. This can either be from data mining or from generating your own data from sequencing or other omics experiments. Once collected, things to note regarding the data includes the data type, what is known regarding the data and what do you want to know about the data. Hypotheses and objectives of the bioinformatic analysis can then be constructed. These will determine the bioinformatic pipeline that needs to be used. The second stage of the analysis is the selection of relevant databases that needs to be incorporated. For example, annotation of protein sequences would require the UniProt database while the annotation of gene sequences would require the GenBank database. Next, we do the homology searching. The tools used for this step depends on the data collected and the database chosen. For sequence-based data, NCBI BLAST would be the go to choice (Madden, 2013). HMM profile data on the other hand can be processed using the HMMER package (Mistry *et al.*, 2013). Often, these tools are embedded in the databases. Finally, manual curation might be necessary when interpreting the results. The use of multiple databases may either verify results or may produce contradicting results. Results from gene annotation can be mapped onto reference pathways to identify pathways that might be in the data collected.

Biological Databases and Types of Data Stored

Sequence Databases

The largest and main databases for biological data are sequence databases. They house digital versions of nucleotide or amino acid sequences. The nucleotide sequences may correspond to whole genomes, genes, expressed sequence tags (ESTs) or ribonucleic acids (RNAs), while amino acid sequences correspond to protein sequences.

The National Center for Biotechnology Information (NCBI) (Acland *et al.*, 2014) houses one of the biggest nucleotide sequence database named GenBank. GenBank is a collection of annotated nucleotide sequences that are publicly available. It supports bibliographic and biological annotation of each nucleotide sequence. NCBI builds GenBank mainly from data submitted by authors, whole-genome shotgun (WGS) and other data from high-throughput sequencing centers. Over 370,000 formerly

Fig. 1 Overview of analysis pipeline that uses biological databases.

described species are being covered by the GenBank database (Benson *et al.*, 2017). Thus, this makes GenBank one of the main reference for nucleotide sequence analyses.

The European Nucleotide Archive (ENA) is a nucleotide sequence repository developed by The European Bioinformatics Institute (EMBL-EBI) (Leinonen *et al.*, 2010). Compared with GenBank, ENA is broader in the types of nucleotide sequences being stored from raw reads to annotated sequences. Data came from both small-scale research laboratories and large-scale sequencing centers. As of 2016, ENA had collected data from 192,000 studies, with 770 million sequence records linked to 200,000 literature publications. ENA are friendly to both users that look for single sequences as well as bioinformaticians that intend to incorporate the ENA database in their analyses pipeline. Both simple and advanced search tools are provided for users at ENA's website. For bioinformaticians that need programmatic access to ENA, the search and download function are being provided by RESTful services (Toribio *et al.*, 2017).

The National Institute of Genetics (NIG) established the DNA Data Bank of Japan (DDBJ) database. Like GenBank and ENA, DDBJ stores nucleotide sequences that were submitted from laboratories and sequencing centers. Submission of next-generation sequencing data is handled by DDBJ Sequence Read Archive (DRA). There is also BioProject to handle the sequencing project metadata and BioSample for handling sample information. In 2013, DDBJ with their partner, the National Bioscience Database Center (NBDC) launched the Japanese Genotype-phenotype Archive (JGA). This database stores the genotype and phenotype data of individuals. Data from JGA is restricted to certain research based on the individuals consent. The DDBJ center is primarily a supercomputing center that provide services to the research community. Their services include web services, submission systems, data retrieval systems, WebApi and DDBJ Read Annotation Pipeline (Mashima *et al.*, 2016). The latest release of DDBJ was on June 2017, Release 109.0 with 874,923,909 entries.

Together with GenBank and ENA, they form the International Nucleotide Sequence Database Collaboration (INSDC; see "Relevant Websites section"). These three databases shares data submitted to them with each other. They all contribute to one pool of nucleotide sequences under the INSDC initiative. They also work together in the development of the database platform and tools. INSDC champions the work of establishing standards, formats and protocols for nucleotide data and metadata. They have become the model for data sharing in the field of life sciences (Cochrane *et al.*, 2016).

UniProt Knowledgebase or UniProtKB is the main protein sequence resource, which is developed and maintained by EMBL-EBI. It consists of two main components, Swiss-Prot and TrEMBL. Swiss-Prot houses over 500 thousand manually annotated and reviewed protein sequences while TrEMBL has over 60 million computationally annotated protein sequences (Consortium, 2017). The annotation of proteins in Swiss-Prot depends on experimental characterization of proteins, thus each entry has a publication attached to it. UniProtKB also houses a non-redundant database of all known protein sequences called UniParc. It currently has over 120 million sequences (Consortium, 2017). UniProtKB is linked to over 150 databases, thus acting as a central hub for organizing protein information. Its accession number plays a key role as a fixed reference for protein sequences, allowing tagging of proteins in informatics applications (Consortium, 2014).

These sequence databases are used as point of reference for either finding your gene or protein sequence of interest. They can also be used for annotating sequences of interest using sequence alignment tools such as NCBI BLAST (Basic Local Alignment Search Tool) (Camacho *et al.*, 2009). In any characterization of sequence, this will be the first method in finding annotation for your sequence of interest. The web links for all mentioned and other sequence databases is in Table 1.

Protein Domain Databases

Protein domain databases are also called protein families databases. They house information on conserved domains in protein sequences. Each domain may be responsible for a specific function, thus it can also be called a protein functional domain (Finn *et al.*, 2016b). Conserved domains may also be structural features of protein sequences. There are many public protein domain databases, of which eleven are listed in Table 2. The databases differ in the method of identifying the conserved domains. We will be exploring some of the features of each database.

Pfam, a protein family database, is essentially a database of multiple sequence alignments. Each protein family entry in Pfam consists of a set of protein sequences called seed sequences (Sonnhammer *et al.*, 1997). The seed sequences are manually curated to make sure they are true members of the protein family. These seed sequences are then aligned to produce the motif logo of the family/domain. The multiple sequence alignment and motif shows which residues are more conserved than others in the domain. Some regions of the domain will be able to tolerate insertions and deletions while some might not. The multiple sequence alignment is profiled using HMMER, a Hidden Markov Model software for the analyses of biological sequences (Finn *et al.*, 2011). A full

TIGRFAM	www.jcvi.org/cgi-bin/tigrfams/index.cgi	J. Craig Venter Institute (JCVI)

alignment of the protein family is built by aligning all members with the HMM profile (Eddy, 1998). This full alignment is useful for identifying features of the protein family such as the distribution of the protein family in living species, the size of the protein family, the level of conservation of the domain of interest as well as identifying homologs of the protein sequence being analyzed. The relationship between the protein family and taxonomic hierarchy can also be studied by generating the taxonomic tree of all the members of the protein family. Each Pfam entry is also cross referenced with literatures and UniProtKB in order to access annotations of the protein family (Finn *et al.*, 2016b). Current version of Pfam is version 31.0, released in March 2017 with 16,712 entries.

New publications that describe protein characterization usually provide one or two proven homologs of the protein. No rules or definitions are provided for the identification of protein homologs from all other organisms. Furthermore, the grouping of protein into functional groups differ from case to case and no fixed heuristics are available that work in most cases. Thus, TIGRFAM was developed to facilitate automated annotations of proteins by providing a library of protein family definitions. Like Pfam, TIGRFAM is a manually curated database. However, TIGRFAM has additional features which make it suitable for automated genome annotation. The annotation of a protein family is always traced back to its original source that is not linked to any computational annotation pipeline. Stringent rules are applied in the selection of seed sequences. Multiple sequence alignment of the seed sequences is checked for misalignments, inconsistent domain architecture and altered active or binding sites. Hidden Markov Models of high quality are then produced from the alignments. The aim is that each HMM produced by TIGRFAM pipeline can be the representative of an expert curator who operates with BLAST-like speeds (Haft *et al.*, 2012). The current release version is 15.0 with 4488 families.

Biologist turn to protein family databases, such as Pfam and TIGRFAM to annotate protein sequences that do not have any matched homologs from protein sequence databases. Both Pfam and TIGRFAM uses HMM profiles, but they differ in their intended use cases. Pfam tries to be as broad as possible to allow for detection of distant homologs to a protein family in the Pfam database. Thus, each protein family in Pfam encodes a small part of the functional domain, with a conservation profile indicative of high sensitivity. The small conserved domain allows the generated HMM to match distant homologs. TIGRFAM on the other hand was developed based on the concept of equivalogs, which are genes or encoded proteins that have a common conserved function since their last common ancestor. This contrasts with the definition of orthologs where only the evolutionary history is concerned (Haft *et al.*, 2003); as such equivalogs may include more than orthologs (i.e., xenologs) and orthologs may not be equivalogs (because of neofunctionalization).

The Conserved Domain Database (CDD) was developed to accelerate the annotation of new protein sequences. Due to the exponential increase in the size of public sequence data, it is impractical to keep aligning new sequences to each sequence in the database for characterization purposes. The strategy took by the developers of CDD was to identify representative sequences for conserved domains. This representative set is unlikely to grow at the same exponential rate as new protein sequences (Marchler-Bauer *et al.*, 2014). CDD collects its protein and protein domain models from Pfam (Sonnhammer *et al.*, 1997), SMART (Letunic *et al.*, 2014), COG Database (Tatusov *et al.*, 2003), TIGRFAM (Haft *et al.*, 2012), NCBI Protein Cluster Database (Klimke *et al.*, 2008) and in house curations efforts (Marchler-Bauer *et al.*, 2003). Each CDD entry is crosslinked to other databases for annotation and search purposes. They include NCBI Entrez Search, Entrez/protein, Entrez/gene, molecular modelling database (MMDB), NCBI Biosystems, PubMed and PubChem (Marchler-Bauer *et al.*, 2014). Current live version of CDD is v3.16 with 56,066 entries, where 12,805 entries are by CDD curation efforts. The entries are grouped into 5697 multi-model superfamilies.

PROSITE is the first database created for identification of protein families or domains. Each entry in the database is a motif descriptor dedicated for identification of protein families. The description can be of two types, patterns or profiles (Sigrist *et al.*, 2002). Patterns are regular expression of short sequence motif that often relate to functionally or structurally important residues. Profiles on the other hand are weight matrices that describe the protein family or domain (Sigrist *et al.*, 2013). Annotation rules in PROSITE are called ProRules. ProRules define annotations relating to protein sequence such as the active site, ligand binding residues and the conditions relating to the annotations (Sigrist *et al.*, 2005). To search protein sequence of interest against PROSITE, the ScanProsite tool can be used. ScanProsite can also search for matches in UniProtKB and Protein Data Bank (PDB) structure database (De Castro *et al.*, 2006). The latest PROSITE release was on 5th July 2017 with 1309 patterns, 1189 profiles and 1208 ProRules.

ProDom is a protein domain database that uses automation instead of relying on manual curation like in Pfam (Finn *et al.*, 2016b) and SMART (Letunic *et al.*, 2014). ProDom algorithm applies automated clustering towards a database of non-redundant sequences from Swiss-Prot, TrEMBL, complete proteomes on the ExPASy server and on the Proteome Analysis pages. The clustering program used is MKDOM2. It uses PSI-BLAST to look for homologous domains amongst the sequences in the database. Sequences that belong to a cluster become a ProDom family and are removed from the database. This is iterated until all the sequences in the database have been exhausted (Servant *et al.*, 2002). In the latest version of ProDom, 3D structure information is used during the generation of ProDom families. 3D structure information is obtained from the Structural Classification of Proteins (SCOP) database (Andreeva *et al.*, 2004). ProDom-CG is a subset of the ProDom database; members of ProDom-CG are restricted to protein sequences from completely sequenced genomes. ProDom also hosts the ProDom-SG, a server for structural genomics. This server identifies protein candidates suitable for crystallization that have potential in having new folds that are yet to be seen in proteins (Bru *et al.*, 2005). The live version of ProDom currently has 1,718,157 domain families (that have at least two members); 426,997 families have links to PDB, 128,882 families have links to PROSITE and 823,801 families have links to Pfam.

PRINTS is a protein 'fingerprint' database. Where other domain databases have entries of single motif representing a conserved domain, 'fingerprint' consist of multiple short motifs that represent a protein family or structural features (Attwood and Beck, 1994). Thus, 'fingerprint' can be more powerful compared to single motif approaches as it depends on multiple motifs. 'Fingerprint' can also annotate the relationships between protein families (domains) as matches to a 'fingerprint' will have multiple domains. Given this, the hierarchical or evolutionary relationship between matches of a 'fingerprint' may also be inferred (Attwood *et al.*, 2012). PRINTS database is currently at version 39.0 with 1950 entries and 11,625 motifs.

SUPERFAMILY is a library of Hidden Markov Models (HMMs) representing protein of known structure. The structural information is obtained from the SCOP database, where proteins are grouped together at several levels; one such level is 'superfamily'. Proteins in a superfamily group shares a common ancestor, thus having functional, structural and sequence similarity. The SUPERFAMILY database was derived from this level because this is the level with most distantly related domains. The framework behind SUPERFAMILY database is HMMs, similar to Pfam (Sonnhammer *et al.*, 1997), SMART (Letunic *et al.*, 2014) and TIGRFAM (Haft *et al.*, 2012) databases. The difference is that SUPERFAMILY only covers proteins with known structure where else the other databases covers all protein sequences (Gough and Chothia, 2002). The SUPERFAMILY database has also been integrated with InterPro (Finn *et al.*, 2016a) and Gene Ontology terms. Abstract from InterPro entries have been imported into SUPERFAMILY. SUPERFAMILY database also provides the users with taxonomic visualization of the families in the database. Users can also search for domain architectures with similar function to find related domains to domains of interest (Wilson *et al.*, 2009). Current SUPERFAMILY database has 1962 entries based on SCOP 1.75 superfamilies.

The Protein Analysis Through Evolutionary Relationships or PANTHER is a database resource of protein families, subfamilies, phylogenetic trees and functions. PANTHER aims to practically infer functions of genes and proteins in large sequence databases. It uses phylogenetic tree approach to extrapolate experimental information from model organisms onto other sequences. Trees generated in PANTHER describes the evolutionary events in gene family histories. One tree is generated for each family. Nodes on the tree are annotated with gene attributes. There are three types of gene attributes annotated in PANTHER. They are 'subfamily membership', 'protein class' and 'gene function'. The trees also include information on speciation and gene duplication events (Mi *et al.*, 2013). Current live version of the database is PANTHER12.0, with 103 genomes, 1,378,820 genes, 14,710 families, and 76,032 subfamilies.

Gene3D derives its domain entries from the CATH (class, architecture, topology & homology) database. CATH is a protein domain structure database. Structures from the Protein Data Bank (PDB) are broken down into smaller domain structures. These domains are then grouped into superfamilies if evidences of common ancestry were found (Sillitoe *et al.*, 2015). From these superfamilies, profile HMMs are generated and put into the Gene3D library.

Protein Structure Databases

Protein structure databases stores coordinate data from protein and other biomolecules structures. The main source for the data are X-ray crystallography experiments. These databases also provide tools for searching proteins that have their structure solved, tools for comparing input proteins with protein structures in the database, visualization tools for generating 3D images of the protein structures in the databases and annotations for each protein structure entry. Advance users may also download raw coordinate data for custom computational biology works. Main databases in this field include the Protein Data Bank, CATH database and SCOP2 database.

The Protein Data Bank (PDB) was founded in 1971 for archiving biomolecular macromolecular crystal structures (Berman *et al.*, 2014). The emergence of new structural biology technologies has forced PDB to evolve into what it is today. Today, after over 46 years, PDB is the largest public database that hosts structural data of biomolecules. PDB employs the best of current data

science technologies and practices. Everything is centralized and various checkpoints are implemented in the PDB pipeline to maintain data integrity and consistency. In 2013, more than 400 million coordinate sets have been downloaded from PDB partner sites. The well-developed data structure and data processing practices has enabled the development of resources for small molecules and ligands such as ChEMBL (Bento *et al.*, 2014), DrugBank (Law *et al.*, 2013), BindingDB (Gilson *et al.*, 2016), BindingMOAD (Ahmed *et al.*, 2014) and PDBind (Liu *et al.*, 2014a). There are also resources developed for protein structure classification and annotation such as CATH (Cuff *et al.*, 2008), SCOP2 (Andreeva *et al.*, 2013) and PDBsum (De Beer *et al.*, 2013). Last but not least, there are specialty annotation resources developed from PDB data such as Protein Data Bank of Transmembrane Proteins (PDBTM) (Kozma *et al.*, 2012), ArchDB (Bonet *et al.*, 2013) and 3did (Mosca *et al.*, 2013).

The CATH (class, architecture, topology & homology) database is a hierarchical database of domains. The lowest level of the hierarchy is the H-level or the homologous superfamily. At this level, the domains share significant sequence similarity, structural similarity and/or functional similarity. The next level up is the T-level or the fold or topology groups. Domains in a group at this level share only structure similarity. Topology groups that have similarities in the arrangement of their secondary structures are then put into the same architecture group. This is also called the A-level. The top level of the hierarchy is the C-level or class level. The groupings at this level depends on the percentage composition of α -helices and β -strands in the domains (Pearl *et al.*, 2003).

SCOP2 database organizes protein structures based on their structure and evolutionary relationships. The main feature of SCOP2 compared to other protein structure database is its focus on protein evolution. The relationship between proteins are represented as a complex network of nodes. There are four major categories of relationships in SCOP2, protein types, evolutionary events, structural classes and protein relationships which have three subtypes: structural, evolutionary and other. SCOP2 uses five levels of evolutionary classification: species, protein, family, superfamily and hyperfamily. At the species level, each gene product is considered as one entity and is represented by its full sequence length. At the protein level, orthologous proteins are grouped together. Conserved residues between proteins forms the next level, which is the family level. Sharing of common structural regions then forms the fourth level, i.e., the superfamily level. The highest level is the hyperfamily level. A domain at this level are shared between superfamilies. These can be smaller than structural domains and was introduced to cater highly populated superfamilies (Andreeva *et al.*, 2013). There are also other protein/biomolecule structure related databases as listed in Table 3.

Non-Coding RNA Databases

Non-coding RNAs or ncRNA are RNAs that do not code for proteins. They are abundant and have important roles in cellular processes. There are several known types of ncRNA including snoRNAs, scaRNAs, miRNAs, siRNAs, snRNAs, exRNAs, piRNAs and long ncRNAs. Small nucleolar RNAs (snoRNAs) are a class of small RNA that assist in chemical modifications of other RNAs such as ribosomal RNAs. A subset of snoRNAs are located in Cajal bodies, thus sometimes called scaRNAs. Micro RNA (miRNA) is a class of small non-coding RNA that can be found in plants, animals and viruses. They are responsible for RNA silencing and post transcriptional regulation of gene expression. Small interfering RNAs (siRNAs) also called short interfering RNAs or silencing RNAs, are nucleotides up to 21 residues long that can interfere with protein translation. They do this by binding to and promoting the degradation of messenger RNAs (mRNAs). Small nuclear RNAs (snRNAs) are confined to the nucleus. They are involved in splicing and other RNA processing (Mattick and Makunin, 2006). Extracellular RNA (exRNA) is a class of RNA found extracellularly. In humans, it has been found in bodily fluids such as blood and saliva. They have many roles depending on types but generally involved in cell-to-cell communication. When the RNA reaches the target cell, it initiates certain biological process

(Benner, 1988). Piwi-interacting RNA (piRNA) is a class of non-coding RNA abundant in animal cells. They form RNA-protein complexes by binding to piwi proteins and are associated with silencing of genetic elements (Seto *et al.*, 2007). lncRNA or long non-coding RNA are nucleotides with over 200 residues but do not encode proteins. They form majority of the human transcriptome but their function remain largely unknown (Mattick and Rinn, 2015).

Generally, ncRNA databases and resources can be grouped into two types, an integrated type which houses annotations of ncRNAs regardless of the subtype and another group which focuses on a specific type of ncRNA. Examples of centralized ncRNA databases are RNAcentral and NONCODE. They provide annotations of the different types of ncRNA by doing data mining and merging of information from other databases. RNAcentral for example, combined information from 42 external databases providing a one stop solution for annotation of ncRNA sequences. There are three main tools in RNAcentral that can be used for finding ncRNA of interest. The tools are text-based searching, sequences-based searching and genome browser. In the text-based searching, one can search based on gene, species, publication and author. The sequence-based searching accepts RNA sequence in FASTA format or an RNAcentral ID. This is similar to searching with web NCBI BLAST (see “Relevant Websites section”). Lastly is the genome browser tool. Currently, there are 12 genomes available in the genome browser. They are *Arabidopsis thaliana*, *Bos taurus*, *Bombyx mori*, *Caenorhabditis elegans*, *Canis familiaris*, *Danio rerio*, *Drosophila melanogaster*, *Homo sapiens*, *Mus musculus*, *Pan troglodytes*, *Rattus norvegicus* and *Schizosaccharomyces pombe*. With the genome browser, one can go to the chromosome of interest to see the genes, transcripts and RNAcentral entries at that location in the genome. The current 8th release has over 13.1 million sequences.

NONCODE is another ncRNA knowledgebase, like the RNAcentral. However, NONCODE has 17 genomes in its genome browser and also does a lot of literature mining to gather ncRNA data. It houses most ncRNA types but focuses on lncRNA (long non-coding RNA). Apart from BLAST and genome browser, NONCODE also provides an ID conversion tool and a pipeline for identification of lncRNA. Other sources of ncRNA can be seen in Table 4.

Applications/Use Cases

The mass amount of biological data housed in various databases is an invaluable resource for fields related to biology: biotechnology, systems biology, bioinformatics, genomics, transcriptomics, proteomics and metabolomics to name a few. In the Fig. 2 below are examples of the databases described in the previous section grouped into their respective types.

Characterization of an Unknown Sequence

Due to the wealth of databases and tools, characterization of unknown sequences, both nucleotides and amino acid sequences can be done relatively quickly. The limitation is the information in the databases itself. If the unknown sequence is truly novel and has

Fig. 2 Example databases for different types of biological data.

not be seen before, *in silico* characterization might then be limited. Given an unknown sequence, the first instinct would be to figure out whether there are similar sequences to the sequence in the databases. Using tools based on homology searching such as BLAST (Camacho, 2015), homologs of the unknown sequence can be identified from the databases. If the homologs are well known, their annotations can be ascribed as putative annotations of the unknown sequence.

Exploring Sequence Patterns and Profiles

Now biologist and researchers in general can explore vast number of domain databases with ease. Each database is equipped with search function and various filters for finding domains of interest. Once the domain of interest is found, users can explore the features and annotations of the domain. Most domain databases provide the motif logo, the multiple sequence alignment and the description of the domain. We can infer a lot from the motif logo; we can observe which residues at which position in the domain are conserved. We can also see alternative residues for positions that are not absolutely conserved in the members of the domain. Databases such as Pfam and TIGRFAM also allows the download of the HMM profile of the domain. With the HMM profile, users can search for sequences that contain the domain or align sequences of interest with the domain. Generating our own HMM profile is also easily done using HMMER. Firstly, we generate a multiple sequence alignment containing the domain of interest. Then using HMMER (hmmbuild), a HMM profile can be generated. This profile can then be searched against sequence databases to find members having the same domain (Mistry *et al.*, 2013).

Mining for Immune Epitopes

There are now databases and resources that provides information on immune epitopes that have been found. From these resources, tools that can predict the existence of immune epitopes in new data have been generated. The main resource for analyzing immune epitopes is the Immune Epitope Database and Analysis Resource (IEDB) (Peters *et al.*, 2005). This resource provides both simple search engine for finding immune epitopes that have been deposited in the database and analysis tools and scripts for prediction of immune epitopes in sequence data. The analysis tools can be found at the website provided in “Relevant Websites section”. There are four categories of analysis tools being provided at IEDB. They are T Cell Epitope Prediction Tools, B Cell Epitope Prediction Tools, Analysis Tools and IEDB Analysis Resource Labs. In the T Cell Epitope Prediction Tools category, there are six tools provided. The use of these tools allows for the identification of peptides that may bind to MHC molecules, peptides that may be T-cell epitopes and the ability of peptides to induce an immune response. In the B Cell Prediction Tools category, there are five tools provided. They allow the prediction of linear B cell epitopes from amino acid sequences, prediction of B cell epitopes from protein structures and structure prediction of antibodies. Tools for analysis of known epitopes have also been developed. The tools can do population coverage analysis, epitope conservation analysis, epitope cluster analysis and mapping of mimotope (Kim *et al.*, 2012).

Global Identification of Protein Post-Translational Modifications

The development of protein sequence databases has accelerated the field of global post-translational modifications identification. There are many types of protein post-translational modifications including phosphorylation, glycosylation, amidation, hydroxylation, methylation and others. Due to the wealth of post-translational modification types, many resources and tools have been developed for the identification of post-translational modifications. As an example, there are 17 or more databases that are related to protein phosphorylation. Choosing appropriate database or resource will depend on the analysis intended or biological question to be answered. For prediction or annotation purposes, there are also databases and tools that can predict multiple post-translational modifications. Some of them include DbPTM 3.0 (Lu *et al.*, 2012), PhosphoSitePlus (PSP) (Hornbeck *et al.*, 2014), PTMcode v2 (Minguez *et al.*, 2014), Compendium of Protein Lysine Modifications (CPLM) (Liu *et al.*, 2014b) and ProteomeScout (Matlock *et al.*, 2014). For doing custom advance bioinformatics, one can download data from post-translational modifications databases and use as training data for machine learning algorithms. Once trained, the machine learning (e.g., neural network or support vector machine) algorithm can identify putative post-translational modifications when input with a new protein sequence data (Gnad *et al.*, 2010).

Characterizing and Functional Assignment of Non-Coding RNAs

Non-coding RNAs from sequencing experiments or data mining efforts can be characterized via several methods depending on what is known about the dataset and the objective of the characterization. If none is known regarding the ncRNA sequences dataset, a good strategy would be to start with a BLAST search against the RNAcentral or NONCODE database. Sequences with identified homologs are ascribed with functions and type of the homologs. Those with identified homologs can be grouped into their putative ncRNA types. Further analysis can be done by doing a sequence search against curated database of a specific ncRNA type. The search will either confirm the previous annotation using RNAcentral (or NONCODE) database or give a different annotation. Assuming the curated database has less errors compared to computationally curated databases, the new function can be assigned to those sequences in the dataset.

Additionally, it may be worthwhile to characterize the ncRNA dataset with all available ncRNA databases. This can be done through at least two strategies. The first strategy is to download all the sequences from the databases. Once downloaded, the sequences can be appended into a single flat file. This flat file can then be converted into a BLAST database using makeblastdb, which is part of the NCBI BLAST software package. Details on generating a BLAST database can be found in the official BLAST guide (see “Relevant Websites section”). The ncRNA sequence dataset can then be searched using the local install of the NCBI BLAST against the custom BLAST database created. The best homologs for each query sequence across all ncRNA databases (source of the custom database) can then be found.

The second strategy is to search each database separately then download all the results. For easier processing, the results can be input into database applications such as mysql or MS Access. With the pooled results, one can now proceed to reduce the results into a non-redundant list. This can be done easily using remove redundant tools in those applications. Some sequences might have different annotations from different database. Manual curation is best at this stage where the investigator can select the best annotation based on what is known regarding the sequences. Once ncRNA sequence databases have been exhaustively searched, sequences that are yet to be annotated can be searched against the Rfam RNA domain database (Daub *et al.*, 2015) or any other RNA motif databases including ATtRACT (Giudice *et al.*, 2016) and RBPBD (Cook *et al.*, 2011).

Future Directions

There are many classes of biological databases today and in each class, there is often more than one database. The protein domain database class for example, twelve databases have been listed in this article. The challenge in having so many public databases of the same class is how to control for overlap of information; this is from the perspective of the database developers. On the other hand, from the user’s perspective, how can one integrate the results from so many databases into his or her analysis pipeline. Each database often has its own ID and set of annotations making the removal of redundant results between databases a not trivial task. Thus, the effort of building a centralized database must continue. In the case of domain databases, InterProScan is one of the efforts for doing search against multiple domain databases (Jones *et al.*, 2014).

Another area of gap in the field of biological databases is the integration of different database class. An integrated database would consist of DNA sequences, RNA sequences, protein sequences, protein structures, protein domains, RNA domains etc. The reason this has yet to be seen is due to the challenges that comes with integration of biological data. The biggest challenge is figuring out the relationships between the different molecular entities. Biological data is big and after integration, it will be even bigger. Thus, there is also the challenge of navigating through the data and data visualization. Finally, is the issue of storage and management due to the sheer size of these integrated databases.

Closing Remarks

Biological databases have been and will always be an essential part of any molecular biology research. The wealth of information gathered since the start of the genomic era is priceless and have led to many new discoveries since then. Developments in biological databases must continue in line with the generation of new biological data.

Introduction

The adaptive immune system is composed of highly specialized cells and processes that recognize “non-self” antigens, mount immune responses to eliminate the antigens or antigen-infected cells, and develop immunological memory through memory B cells and memory T cells that leads to an enhanced response to subsequent encounters with the same antigens. Two arms of adaptive immunity, the humoral immunity mediated by B cells and the cell-mediated immunity mediated by T cells, work closely to combat infection and malignancy in an antigen specific manner. Major histocompatibility complex (MHC) proteins play a vital role in the regulation of cell-mediated immune responses. MHC class I molecules are found on every nucleated cell of the body, while MHC class II molecules are expressed on specialized cells, including professional APCs such as B cells, macrophages and dendritic cells (Janeway, 2005). They bind short peptides derived from protein antigens through proteolytic mechanisms and subsequently present MHC-peptide complexes on the cell surface for recognition by T cells. T cells identify foreign antigens through their T-cell receptors (TCRs), which interacts with MHC-peptide complexes in conjunction with CD4 or CD8 co-receptors (Meuer *et al.*, 1982; Wang and Reinherz, 2002). MHC class I antigen processing pathway steps include proteasome cleavage of proteins into shorter peptides, translocation of peptides into the endoplasmic reticulum (ER) by TAP (the transporter associated with antigen processing), optional ER trimming by aminopeptidases, insertion of peptides, typically 8–11 amino acid residues in length, into the binding groove of MHC molecules, and transport of peptide-MHC complexes to the cell surface for presentation to CD8 + T cells (Purcell and Gorman, 2004; Strehl *et al.*, 2005). In humoral immunity, B cells produce antibodies to eliminate extracellular microorganisms and prevent the spread of infection. T lymphocytes expressing the CD4 co-receptor recognize MHC class II molecules complexed to peptides generated from endogenous cellular proteins that are typically 8–30 amino acids in length and are often nested sets of peptides with a core sequence shared among them (Rudensky *et al.*, 1991; Engelhard, 1994; Bozzacco *et al.*, 2011). The recognition of peptide-MHC class II complexes by CD4 + T cells, stimulating them to make proteins that stimulate the B cells to differentiate into antibody secreting cells. Thus the activation of B cells is triggered by antigens and usually requires helper T cells (Janeway, 2005). B cells identify antigens through B-cell receptors, which recognize discrete sites on the surface of target antigens called B-cell epitopes (Van Regenmortel, 2009). Peptides that are presented by MHC and recognized by T-cells are termed T cell epitopes. They are important targets of adaptive immune responses and rational vaccine design. This article focuses on the MHC binding peptides and T cell epitopes.

Identification of T cell epitopes is essential in the development of epitope-based vaccines. One of the key steps in T-cell epitope prediction is the prediction of MHC binding, as it is considered the most selective step in T cell recognition. The challenge in the identification of broadly protective vaccine targets stems from two principal sources – the diversity of pathogens and the diversity of human immune system. HLA (Human Leukocyte Antigen, human MHC) are among the most polymorphic human proteins, with more than 12,000 known HLA Class I alleles and 4700 HLA class II variants as of Dec 2017 (Robinson *et al.*, 2015). To handle HLA polymorphism, the concept of HLA supertypes was proposed to group HLA alleles showing similar peptide binding specificity into supertypes (Sidney *et al.*, 1996; Sette and Sidney, 1999). The ideal vaccine targets are conserved immune epitopes that are broadly cross-reactive to viral subtypes and protective of a large human population (Zhang *et al.*, 2014). In this article we reviewed *in silico* and *in vitro* methods for immune epitope discovery.

In Vitro Methods for Identification of MHC Ligands and T Cell Epitopes

In Vitro Discovery of MHC Ligands

MHC binding to a potential peptide can be tested *in vitro* using binding assays or Mass spectrometry (MS) based methods. Note that MHC binding does not guarantee T cell reactivity. In binding assays, purified MHC proteins or TAP deficient cells lines are used to test peptide binding to specific MHC molecules. These assays are only useful in testing MHC/peptide binding, a prerequisite for T-cell activation. It does not guarantee T cells will recognize the binding peptide as antigen. For example, TAP-deficient T2 cell HLA stabilization assay was used to confirm 10 HPV (human papillomavirus) E6 and E7 peptides that bind to HLA-A*0201 (Riemer *et al.*, 2010).

MHC-peptide complexes may be immunoprecipitated from target cells. Peptides may be released from MHC using fractionation (e.g., using HPLC, the physical separation capabilities of liquid chromatography). These peptides can be analyzed by MS analysis that produces detailed information of the MHC ligandome. MS based ligand discovery physically detect the peptides that are naturally processed and presented on the cell surface. We refer to these peptides as “eluted peptides”. The immunogenicity of these peptides needs further *in vivo* and *in vitro* testing. MS based assays require extensive optimization for pure MHC-Peptide complex isolation. MS analysis also requires rare expertise, which are not directly applicable to all laboratories (Bozzacco *et al.*, 2011; Abelin *et al.*, 2017).

In Vitro Discovery of T Cell Epitopes

T cell epitope discovery without the help of bioinformatics prediction algorithms applies T cell immunogenicity assays on overlapping peptides. These synthesized peptides are typically 15–16 amino acids (aa) in length with 10aa overlap and cover the protein sequence of the whole pathogen. They are pooled together to be tested. T cells can be tested *ex-vivo* from previously infected, immune donors or after a few rounds of stimulation in cell culture from naïve donors. Generation of an antigen specific T cell line may take up to four weekly antigen stimulations. Cloning of a T cell may require further culture for up to two months of hands-on work.

In T cell reactivity testing, multiple experimental assays including intra-cellular cytokine staining, proliferation assays and Elispot assays are available to test peptide epitope reactivity. In intra-cellular cytokine staining, T cells produce cytokines such as IFN γ , TNF α and IL-2 after epitope recognition and activation. After a brief *ex-vivo* culture with possible reactive peptides or peptide pools, T cells are stained for these cytokines *in vitro* using specific antibodies linked to fluorochromes. Cell membranes need to be permeabilized for antibody access using detergents, which makes the assay less sensitive than other available assays. Golgi blocking agents can be used briefly in culture for cytokine deposition in the cytoplasm. After antibody staining the cells are analyzed using a flow-cytometer (Ott *et al.*, 2017).

In proliferation assays, T cells start proliferating 2–3 days after antigen recognition. T cell proliferation can be measured using tritiated Thymidine incorporation or dilution of cell permeable marker dyes such as CFSE (Carboxyfluorescein succinimidyl ester) by flow cytometry. These assays are sensitive however require long term cell culture (Mellor *et al.*, 2002).

Elispot assays utilize cytokine capture antibody coated plates. T cells produce cytokines such as IFN γ , TNF α and IL-2 after epitope recognition and activation. T cells can be stimulated in this cytokine capture antibody coated plates up to 48 h. After removal of T cells, the captured cytokines on plates are detected by a sandwich assay utilizing a biotinylated secondary cytokine specific antibody and streptavidin enzyme conjugate. These assays produce spots, which represents each cytokine producing T cells. Spot forming cells can be calculated from each assay and will give accurate antigen specific T cell frequency in a sample (Keskin *et al.*, 2015).

In Silico Methods for Epitope Identification

The advancement in high throughput methods such as whole-genome sequencing and in bioinformatics led to the identification of potential vaccine targets without the need for growing the pathogen. The concept of reverse vaccinology supports identification of vaccine targets by large-scale bioinformatics screening of entire pathogenic genomes followed by experimental validation (Rappuoli, 2000; Mora *et al.*, 2003; Rappuoli *et al.*, 2016).

Publicly available bioinformatics resources include biological databases that organize and catalog immune epitopes and their related information as well as computational systems that model the biological processes involved in antigen processing and presentation, i.e., proteasome cleavage, TAP transportation, and MHC binding.

Databases Hosting Immune Epitopes

Table 1 summarizes immune epitopes databases that are publically available. Some are general-purpose databases, including SYFPEITHI, the Immune Epitope Database and Analysis Resource (IEDB), MCHBN, and Dana-Farber Repository for Machine Learning in immunology (DFRMLI), hosting MHC binding peptides and immune epitopes from various types of antigens. Some host immune epitopes from tumor antigens, such as the Cancer Immunome database and Tantigen. Some host immune epitopes from specific viruses, such as EBVdb (Epstein-Barr virus T cell antigen database), FLAVIdB (Flaviviruses database), FluKB (Influenza virus knowledge-base), HPVdb (Human Papillomavirus T cell Antigen Database), Los Alamos hepatitis C immunology database, and Los Alamos HIV Molecular Immunology Database.

DFRMLI hosts standardized data sets of HLA-binding peptides with all binding affinities mapped onto a common scale and a list of experimentally validated naturally processed eluted peptides and non-binding peptides derived from tumor or virus antigens (Zhang *et al.*, 2011). Some of the data in DFRMLI were aggregated from publically available databases such as MHCPEP (Brusic *et al.*, 1994), IEDB, CBS (Center for Biological Sequence Analysis). Some data are our in-house data and the validation data sets were made of carefully selected independent data. These data sets were used to support the 1st and 2nd machine learning competitions in immunology in 2011 and 2012 (Zhang *et al.*, 2011). IEDB established in 2004 catalogs experimentally characterized B and T cell epitopes, MHC binding peptides, and data on corresponding experimental assays. It also hosts computational tools for immune epitope prediction and analysis (Vita *et al.*, 2015; Fleri *et al.*, 2017). Domain experts manually curated the data in IEDB to ensure quality and data completeness. The IEDB intentionally does not contain HIV (human immunodeficiency virus) epitopes as they are archived in the Los Alamos HIV Molecular Immunology Database (Altman and Safritz, 1998). MCHBN is a database hosting experimentally validated T cell epitopes, binding peptides to MHC and TAP, and non-binding peptides to MHC and TAP. MCHBN also provides bioinformatics tools for the analysis and retrieval of information like mapping of antigenic regions, creation of allele specific dataset, BLAST search, various diseases associated with MHC alleles etc (Lata *et al.*, 2009). SYFPEITHI is among the earliest online database that host immune epitopes (Rammensee *et al.*, 1999; Schuler *et al.*, 2007). It

Table 1 Online databases hosting immune epitopes listed in alphabetical order. The information is up to date as of Dec 2017

Database	Description of content	URL
Cancer Immunome Database	Four data tables containing over 400 T cell epitopes identified in tumor antigens	www.cancerresearch.org/scientists/events-and-resources/peptide-database
Dana-Farber Repository for Machine Learning in Immunology (DFRMLI)	MHC class I and II binding peptides, eluted peptides, non-binding peptides	projects.met-hilab.org/DFRMLI/
EBVdb, Epstein-Barr virus (EBV) T cell antigen database	610 T cell epitopes and 26 HLA ligands from EBV antigens	projects.met-hilab.org/ebv
FLAVIdb, Flaviviruses database	184 verified T-cell epitopes, 201 verified B-cell epitopes	cvc.dfci.harvard.edu/flavi/
FluKB, a knowledge-base for influenza viruses	357 T-cell epitopes, 685 HLA binding peptides, 16 naturally processed MHC ligands, and 28 influenza antibodies and their structurally defined B-cell epitopes	research4.dfci.harvard.edu/cvc/flukb/
HPVdb, Human Papillomavirus (HPV) T cell Antigen Database	191 T cell epitopes and 45 HLA ligands from HPV antigens	projects.met-hilab.org/hpv
IEDB	422,219 peptide epitopes, 2553 non-peptidic epitopes, T cell and B cell assays, MHC binding assays etc.	www.iedb.org/
Los Alamos hepatitis C immunology database	383 CD8 + T cell epitopes, 222 CD4 + T cell epitopes, and 60 antibody binding sites from HCV proteins for human, mouse, chimpanzee, and rat	hcv.lanl.gov/content/immuno/immuno-main.html
Los Alamos HIV Molecular Immunology Database	9821 CD8 + T cell epitopes, 1578 CD4 + T cell epitopes, and 3306 antibody binding sites from HIV proteins for human, macaque, chimpanzee, mouse etc.	www.hiv.lanl.gov/content/immunology/
MHCBN	6722 T cell epitopes, 4022 non-binding peptides, 1022 TAP binding peptides	crdd.osdd.net/raghava/mhcbn/
SYFPEITHI	>7000 MHC class I and II binding peptides	www.syfpeithi.de/
Tantigen	>1000 HLA class I and II binding peptides, eluted peptides, and T cell epitopes from tumor antigens	projects.met-hilab.org/tadb or cvc.dfci.harvard.edu/tantigen/

allows users to search for MHC ligands, peptide binding motifs, natural ligands, and T cell epitopes by specifying MHC alleles, source proteins/organisms, etc., It also supports MHC binding prediction.

The identification of tumor antigens is a high priority in cancer research and is an essential component in developing immune-based strategies to combat cancer. The following databases introduced are useful resources for the study of immune responses against tumors. The Cancer Immunome database is a continuation of the SEREX database, maintained by the Ludwig Institute for Cancer Research since 1997, in a more organized form. The database contains T cell epitopes in tumor antigens that are classified based on their tumor specificity into four data tables (Jongeneel, 2001; Vigneron *et al.*, 2013). All immune epitopes in the database have been documented to elicit immune responses in cancer patients. Tantigen is a database of human tumor T cell antigens that catalogued more than 1000 tumor peptides. The peptides are labelled as one of four categories: (1) peptides measured *in vitro* to bind the HLA, (2) peptides found to bind the HLA and to elicit an *in vitro* T cell response, (3) peptides shown to elicit *in vivo* tumor rejection, and (4) peptides processed and naturally presented as defined by physical detection. The Tumor T Cell Antigen Database (TANTIGEN) is a data source and analysis platform for cancer vaccine target discovery focusing on human tumor-derived HLA ligands and T cell epitopes. It contains 4006 curated antigen entries representing 251 unique proteins, information on experimentally validated T cell epitopes and HLA ligands, antigen isoforms, antigen sequence mutations, and tumor antigen classification. TANTIGEN provides a rich data resource and tailored analysis tools for tumor associated epitope and neoepitope discovery studies (Olsen *et al.*, 2017).

Some viruses such as Epstein-Barr virus (EBV) and human papillomaviruses (HPVs) are the causes of many cancers, which some such as influenza viruses, flaviviruses, and HIV cause various infectious disease. To facilitate diagnosis, prognosis and characterization of these diseases, it is necessary to make full use of the immunological data on the viruses. Epstein-Barr virus (EBV) T cell antigen database is a data source and analysis platform for EBV immune target discovery by focusing on EBV antigens that contain T cell epitopes (Zhang *et al.*, 2015). It hosts 2622 curated EBV antigen sequences, 610 T cell epitopes and 26 HLA ligands. FLAVIdb combines antigenic data of flaviviruses, specialized analysis tools, and workflows for automated complex analyses focusing on applications in immunology and vaccinology (Olsen *et al.*, 2011). It contains 12,858 entries of flavivirus antigen sequences, 184 T-cell epitopes, 201 B-cell epitopes, and four representative molecular structures of the dengue virus envelope protein. FluKB provides access to more than 400,000 curated influenza protein sequences, known epitope data (357 verified T-cell epitopes, 685 HLA binders, and 16 naturally processed MHC ligands), and a collection of 28 influenza antibodies and their structurally defined B-cell epitopes (Simon *et al.*, 2015). HPVdb is a data mining system for knowledge discovery in HPV with applications in T cell immunology and vaccinology. It contains 2781 curated antigenic proteins derived from 18 genotypes of high-risk HPV and 18 genotypes of low-risk HPV, 191 T cell epitopes and 45 HLA ligands (Zhang *et al.*, 2014). Los Alamos hepatitis C immunology database contains T-cell epitopes and antibody binding sites in hepatitis C virus (HCV) for human and multiple animal models, as well as relevant retrieval

and analysis tools (Yusim *et al.*, 2005). The HIV Molecular Immunology Database provides an annotated collection of HIV-1 cytotoxic and helper T-cell epitopes and antibody binding sites (Immunology, 2016).

Prediction Systems for Proteasome Cleavage, TAP Binding, and MHC Binding

Computational tools that model the proteolytic activities of the proteasome and TAP binding can be integrated with prediction systems for MHC class I binding peptides to improve the performance of *in silico* prediction of T-cell epitopes. NetChop predicts cleavage sites of the human proteasome using artificial neural network (ANN) models trained on data from *in vitro* digestion experiments with constitutive proteasomes and MHC Class I ligand data that reflect immunoproteasome specificity (Kesmir *et al.*, 2002; Nielsen *et al.*, 2005). NetChop team maintains the tool and updated it periodically. The latest version is NetChop v3.1. MAPPP models two essential steps in endogenous antigen processing pathway, the proteasome cleavage and MHC binding. FRAGPREDICT that predicts the proteasome cleavage sites using motifs encoding cleavage-enhancing and -inhibiting amino acids is the part that models proteasome cleavage in MAPPP (Holzhutter *et al.*, 1999). PAPProC (Prediction Algorithm for Proteasomal Cleavages) is an online prediction system for cleavages by constitutive proteasomes of human and yeast based on experimental cleavage data (Nussbaum *et al.*, 2001). Pcleavage is a prediction system for constitutive as well as immunoproteasome cleavage sites using a support vector machine (SVM) based method (Bhasin and Raghava, 2005). Saxova and co-authors evaluated the performance of PAPProC, FRAGPREDICT and two versions of NetChop, v1.0 and v2.0 and found that NetChop v2.0 performed the best (Saxova *et al.*, 2003) (Tables 2).

TAP is a transmembrane protein that transports antigenic peptides into the ER. It has been shown that the efficiency of TAP-mediated translocation of a peptide correlates positively to its TAP binding affinity (Brusic *et al.*, 1999). Peptides of 8–16 amino acids and have sufficient TAP binding affinity are efficiently translocated by TAP into the ER, while longer peptides may be transported but with lower efficiency (Saveanu *et al.*, 2005). SVMTAP employs a matrix-based method and support vector regression to predict peptides transported by TAP (Donnes and Kohlbacher, 2005). TAPPred is based on cascade SVM using sequence and properties of the amino acids (Bhasin and Raghava, 2004) (Table 3).

MHC binding is the most selective step in the antigen presentation pathway. Quite a few online prediction systems have been developed for the prediction of peptide binding to MHC molecules based on algorithms including binding motifs, quantitative matrices, and machine learning methods such as ANN models and support vector machines. In addition there has been effort to develop a prediction algorithm based on naturally processed and presented MHC eluted peptide epitopes detected by MS together with gene expression and protein processing (Abelin *et al.*, 2017). While the prediction systems listed in Table 4 were designed for different purposes with various methods, all of them have peptide binding predictions implemented as specific modules. MAPPP, ProPred-I, and RANKPEP predict proteasomal cleavage sites and MHC binding. MULTIPRED2 predicts peptide binding to HLA supertypes, and BIMAS predicts peptide binding as half-time dissociation (off-rate).

BIMAS is one of the first online tools that predicts 8-mer, 9-mer, or 10-mer binding peptides using class I mouse and human MHC binding motifs (Parker *et al.*, 1994). SYFPEITHI predicts MHC class I and class II binding peptides in human, mouse and rat based on allele-specific peptide motifs (Schuler *et al.*, 2007). The MHC binding prediction part of MAPPP identifies potential 8-mer, 9-mer and 10mer peptides that bind human, mouse and bovine MHC class I alleles with the option to use either BIMAS matrix or SYFPEITHI matrix for prediction (Hakenberg *et al.*, 2003). Note that MAPPP (BIMAS) and MAPPP (SYFPEITHI) showed identical predictions to BIMAS and SYFPEITHI, respectively (Lin *et al.*, 2008). RANKPEP predicts binding peptides of 88 MHC class I and 50 MHC class II alleles in human and mouse using position specific scoring matrices (PSSMs) (Reche *et al.*, 2002, 2004). There is option to add in the proteasome cleavage step in the prediction.

TEPITOPEpan	Predicts binding peptides to HLA-DR alleles	datamining-iip.fudan.edu.cn/service/TEPITOPEpan/TEPITOPEpan.html

NetMHC v4.0 predicts peptides that bind 81 different HLA-A, -B, -C and -E alleles as well as 41 MHC class I alleles of monkey, cattle, pig, and mouse. It employs a sequence alignment method based on ANN that allows insertions and deletions in the alignment (Nielsen *et al.*, 2003; Andreatta and Nielsen, 2016). NetMHCpan v4.0 predicts peptides that bind any MHC class I molecule of known sequence based on an ANN model trained using pseudo-sequences representing peptide/MHC interactions (Nielsen *et al.*, 2007a,b; Jurtz *et al.*, 2017). The pseudo-sequences that capture the specific HLA-peptide interaction by combining each amino acid of the peptide with the variable amino acids of its positional environment was first proposed in Brusci *et al.* (2002). NetMHCpan v4.0 was trained on a combination of quantitative MHC binding data and MS derived MHC eluted ligands (Hoof *et al.*, 2009; Jurtz *et al.*, 2017). PickPocket v1.1 predicts binding peptides of any known MHC class I molecule using position specific weight matrices that capture receptor-pocket similarities between MHC molecules. Predictions can be made for HLA-A, -B, -C, -E and -G alleles as well as MHC class I alleles in mouse, cattle and pig (Zhang *et al.*, 2009). NetMHCcons a consensus method for MHC class I binding predictions integrating three methods, NetMHC, NetMHCpan and PickPocket (Karosiene *et al.*, 2012). NetMHCII v2.2 predicts binding peptides for 14 HLA-DR alleles, six HLA-DQ, six HLA-DP, and two mouse H2 class II alleles. It employs an ANN-based alignment method, NN-align, trained using an algorithm that incorporates information on the residues flanking the peptide-binding core (Nielsen *et al.*, 2007a,b; Nielsen and Lund, 2009). NetMHCIIpan v3.1 predicts binding peptides of MHC class II molecules in human (HLA-DR, HLA-DP and HLA-DQ) and mouse (H2) (Karosiene *et al.*, 2013; Andreatta *et al.*, 2015).

IEDB MCH class I tool predicts binding peptides of MHC class I alleles in human and multiple animals. It allows users to choose from a number of prediction methods including Stabilized matrix method (SMM) (Peters and Sette, 2005), NetMCHpan, NetMHC, NetMHCcons, PickPocket and so on. IEDB MCH class II tool predicts binding peptides of MHC class I alleles in human and multiple animals. It allows users to choose from a number of prediction methods including the consensus method (Wang *et al.*, 2008), NetMHCII, NetMHCIIpan and so on. MULTIPRED2 screens for peptide binding to multiple alleles belonging to HLA class I and class II supertypes as well as to alleles belonging to an individual's genotype. The prediction engines used are NetMHCpan and NetMHCIIpan. In total MULTIPRED2 performs binding predictions on 1077 alleles belonging to 26 HLA supertypes (Zhang *et al.*, 2011).

ProPred-I predicts binding peptides of 47 MHC class-I alleles in human, mouse and cow using quantitative matrices. ProPred-I provides the option to filter out the peptides with predicted proteasomal cleavage sites (Singh and Raghava, 2003). The ProPred1 predictions were found highly correlated with BIMAS predictions for five HLA-I alleles (HLA-A*02:01, -A*03:01, -A*11:01, -A*24:01, and -B*08:01,) as some of the BIMAS matrices were adopted by ProPred1 (Lin *et al.*, 2008). ProPred predicts binding peptides of 51 HLA-DRB1 and -DRB5 alleles using quantitative matrices (Singh and Raghava, 2001). SVMHC predicts of 9-mer and 10-mer peptides that bind multiple MHC class I alleles in human and mouse using SVM based methods. It also predicts binding peptides to HLA-DRB1 alleles using PSSMs from TEPITOPE, a widely used method containing PSSMs that cover 51 different HLA-DR alleles (Sturniolo *et al.*, 1999; Donnes and Kohlbacher, 2006). TEPITOPEpan was built by extrapolating from the

HLA-DR alleles with known binding specificities in TEPITOPE to the HLA-DR molecules with unknown binding specificities based on pocket similarity (Zhang *et al.*, 2012). TEPITOPEpan is able to predict binding peptides of more than 700 HLA-DR alleles.

With many MHC binding prediction systems available, the next question is how to choose the most suitable one for predicting binding to a given MHC molecule. Several groups have reported their effort in assessing performance of computational methods that predict peptide binding to several common MHC class I (Peters *et al.*, 2006; Lin *et al.*, 2008; Gowthaman *et al.*, 2010; Zhang *et al.*, 2011; Trolle *et al.*, 2015) and II alleles (Lin *et al.*, 2008). Machine learning competition in immunology organized by Dana-Farber Cancer Institute evaluated the performance of 20 computational methods in predicting 9-mer and 10-mer peptides binding to HLA-A*01:01, A*02:01, and B*07:02. The evaluation data sets used in the competition are available at DFRMLI. It was found that NetMHC, NetMHCpan, and NetMHCcons demonstrated the best performance overall (Zhang *et al.*, 2011). Lin *et al.* (2008) compare the performance of 30 computational methods in predicting peptides binding to seven HLA class I alleles, A*0201, 0301, 1101, 2402, B*0702, 0801, and 1501. In general they found the prediction methods for A*0201, 0301, 1101, B*0702, 0801, and 1501 have excellent, and for A*2402 moderate classification accuracy (Lin *et al.*, 2008). Gowthaman *et al.* evaluated eight prediction systems in predicting peptides binding to seven HLA class I alleles, A*0101, 0201, 0301, 1101, 2402, B*0702, and 0801. It was found that NetMHC, NetMHCpan, and IEDB showed better overall efficiency (Gowthaman *et al.*, 2010). In Lin *et al.* (2008), 21 HLA class II prediction methods were evaluated for their performance in predicting binding peptides of seven common HLA-DR allele, DRB1*0101, 0301, 0401, 0701, 1101, 1301, and 1501. It was found that the HLA class II predictors do not match prediction capabilities of HLA class I ones. It is more difficult to predict MHC class II binding as, unlike MHC class I molecules, binding grooves of a MHC class II molecules have open ends allowing them to accommodate the 9-mer binding core of the peptides inside while peptide termini protrude outside of the grooves (Stern *et al.*, 1994). Not a single method is consistently the best for all the alleles and users have to select the suitable predictors by referring to the detailed findings in the papers. A framework that supports automated benchmarking of MHC binding prediction tools was developed. It runs weekly benchmarks on data that are newly entered into IEDB to provide up-to-date performance evaluations available at the website provided in "Relevant Website section" (Trolle *et al.*, 2015; Andreatta *et al.*, 2017).

Discussion

Immune epitopes are the targets of adaptive immune responses and rational vaccine design. We reviewed *in silico* and *in vitro* methods for immune epitope discovery. *In silico* methods include databases of immune epitopes, prediction systems for proteasome cleavage, TAP binding, and MHC binding. These *in silico* tools support downstream *in vitro* and *in vivo* studies. Publically available immune epitope databases allow both scientists and clinicians to utilize target genome information to support rational vaccine design and development. The availability of curated MHC binding data and T cell epitopes in turn improves target selection. These technologies are finding real life applications, for example the vaccines against HIV, the causative agent of AIDS (Stephenson *et al.*, 2016). The vast genetic diversity of HIV type 1 (HIV-1) envelope glycoprotein poses challenges in developing a global vaccine. Currently a mosaic HIV virus vaccine that contains mosaic HIV virus components designed utilizing Los Alamos HIV database to provide global virus coverage is in clinical trial (Ad26-env mosaic vaccine) (Nkolola *et al.*, 2014). Similar efforts are underway to develop universal Influenza vaccines utilizing FluKB and vaccines against cancer causing viruses such as HPV utilizing HPVdb (Riemer *et al.*, 2010; Keskin *et al.*, 2011; Keskin *et al.*, 2015). Computational tools and databases also play a role in support of developing personalized neo-antigen based cancer vaccines. Neo-antigens arise from tumor specific mutations, these epitopes are exclusively tumor specific and they circumvent T cell tolerance against self-epitopes (Fritsch *et al.*, 2013). Next generation sequencing and utilization of T cell epitope prediction algorithms provide tools to design cancer vaccines against an individual's own tumor from the Tumor gene sequencing data, one patient at a time (Melief, 2017; Ott *et al.*, 2017; Sahin *et al.*, 2017). These personalized cancer vaccines provide a leap in cancer treatment in the direction of personalized immunotherapy.

Future Directions

Identification of peptide presentation and processing rules through MS analysis of HLA binding peptides is currently perfecting epitope prediction algorithms (Abelin *et al.*, 2017). Next-generation sequencing (NGS) enables rapid and accurate deduction of the genomics of viruses, bacteria and cancers, in which we can identify mutated new epitopes (neoepitopes) (Ott *et al.*, 2017). Many existing prediction systems predict MHC binding peptides and MS analysis of these peptides detect the presentation of them on cell surface, however not all of these presented peptides are seen by T cells as antigens. Those silent, stealth epitopes complicate reverse vaccinology. There are efforts to improve the prediction of antigenicity of epitopes, however it requires large amount of validated antigen data. "T cell receptor (TCR) sequences are very diverse, with many more possible sequence combinations than T cells in any one individual" (Davis and Bjorkman, 1988; Shortman *et al.*, 1990; Qi *et al.*, 2014). Technologies to rapidly detect T cell epitopes are currently in development (Gee *et al.*, 2018). The next advancement in rapid vaccine design would be algorithms that can predict the immunogenicity of HLA binding peptides. Combinations of all three of these technologies, (i) rapid NGS sequencing to deduce protein coding sequences, (ii) HLA allele specific, predictive epitope processing and presentation algorithms and (iii) development of TCR specific antigenicity prediction would finally enable rapid vaccine design through reverse vaccinology.

Conflict of Interest

The authors declare that they have no conflict of interest.

Introduction

Noncoding RNAs (ncRNAs) are a family of RNA molecules that do not code for proteins. A large number of studies on cell proliferation, metabolism, epigenetic, and physiological processes (Gao *et al.*, 2017) have shown their role specific to regulation leading to a number of molecular mechanisms (Wang and Chang, 2011). Essentially ncRNAs are classified into small ncRNAs, which include microRNAs (miRNAs) and circular RNAs (CiRNAs); and long intergenic noncoding RNAs (lincRNAs) and long noncoding RNAs (lncRNAs) (Shah *et al.*, 2016). Recent human whole transcriptomic data have revealed that less than 2% of the genome encodes protein-coding transcripts, even though the majority of the genome is actively transcribed into ncRNAs under multiple physiological conditions (Liz and Esteller, 2016). Diseases that are associated with an altered transcriptome are not only restricted to the abnormal production of protein-coding RNAs, but also in the expression of many noncoding RNAs. Although there has been an increase in evidence for the link between ncRNAs and diverse human diseases, studies on ncRNA–protein association studies have caught an immense interest and have opened a new possibility in identifying cause for diseases (Wapinski and Chang, 2011). This has allowed us to improve next generation sequencing (NGS) tools for identifying functional moieties, for example, pseudogenes in making novel proteins (Shidhi *et al.*, 2015).

Background

With transcriptome and high-throughput sequencing (HITS) analysis revealing a large number of ncRNAs in various organisms, studies on their functional characterization have resulted in data on interactions with their RNA peers, DNA, or proteins (Novikova *et al.*, 2013). While the ncRNAs are believed to be associated with a wide number of human diseases including development, imprinting, mental and psychiatric disorders, and tumor growth (Liu *et al.*, 2012), they are also associated with plant growth, environmental stress, biological processes and development, besides capacity to encode small peptides (Lv *et al.*, 2016). The miRNAs play an important role in posttranscriptional gene regulation by either translation repression or directing the degradation of complementary mRNA targets. The miRNA molecules are derived from the primary miRNAs (pri-miRNAs) and negatively regulate the gene expression in various plants and animals. It was also known that the plant pri-miRNAs containing small open reading frames (ORFs) have the capacity to encode regulatory peptides (Lauressergues *et al.*, 2015). It has been reported that primary transcripts of plant miRNAs encode peptides (miPEPs) and increases the transcription of other associated miRNAs (Couzigou *et al.*, 2015). Unlike miRNAs, which are short and ca. 22–23 bp, lncRNAs are more than 200 nucleotides without ORFs. Most of these transcripts are coded by RNA polymerase II, either spliced or poly-adenylated. Whereas the ncRNAs play a role as key regulators in life cycle of the organism, this concept of regulation driven by ncRNAs has begun to be understood in mitochondria and chloroplasts as well (Lung *et al.*, 2006). For example, nuclear-encoded miRNAs were found to be associated with mitochondrial transcription and translation in eukaryotes (Rackham *et al.*, 2011). In addition, ncRNAs of various sizes are thought to play a role in RNA interference or antisense pathways (Kaczmarek *et al.*, 2017). Like the traditional proteins piggy-backing from nucleus/cytoplasm to mitochondria, the ncRNAs also operate in the nucleus or cytoplasm while targeting the mitochondria. With regards to numerous ncRNAs identified in chloroplasts, they have been known to map to the plastid genome (Dietrich *et al.*, 2015) and play a role in various functions of the plant cell. A broad classification of ncRNAs based on their mode of function is presented in Fig. 1.

While transcription of ncRNAs is done by RNA polymerase II, the transcripts are capped and polyadenylated (Kim, 2005). Classes of small RNAs such as short interfering RNAs (siRNAs), piwi-interacting RNAs (piRNAs), and miRNAs found in eukaryotes regulate endogenous genes and defend the genome from invasive nucleic acids. For example, in 1993, the first miRNA, *lin-4* from *Caenorhabditis elegans* was discovered by Ambros, which is known to control developmental timing (Bartel, 2004). In addition, their role in genome defense is documented (Mello and Conte, 2004).

The pri-miRNA transcribed from DNA is excised by Drosha, to produce the pre-miRNA (Fig. 2). The pre-miRNA is exported to the cytoplasm by exportin-5 and spliced by Dicer to generate a miRNA duplex, which is then assembled into the RNA-induced silencing complex (Bartel, 2004). The miRNAs modulate target mRNA translation by complementary

Non-coding RNAs in hepatitis C-induced hepatocellular carcinoma: Dysregulation and implications for early detection, diagnosis and therapy. *World Journal of Gastroenterology* 19(44), 7836–7845. Dey *et al.*, 2012. Non-micro-short RNAs: The new kids on the block. *Molecular Biology of the Cell* 23(24), 4664–4667. Abbreviations: ncRNA: noncoding RNA, miRNA: micro RNA, piRNA: piwi RNA, siRNA: small interfering RNA, tiRNA: transcription initiation RNA, tRNA: transfer RNA, snoRNA: small nucleolar RNA, snRNA: small nuclear RNA, scRNA: small cytoplasmic RNA, *cis*-lncRNA: *cis*-acting long noncoding RNA, *trans*-lncRNA: *trans*-acting long noncoding RNA, ceRNA: competing endogenous RNA.

Fig. 2 Illustrative representation of formation of mature miRNAs. The primary miRNAs synthesized in nucleus are exported to cytoplasm by exportin later spliced by Dicer before assembly.

binding, within the 3' UTR, 5' UTR, or coding regions. The miRNAs also function by binding to DNA promoters, acting as RNA decoys or through direct binding of target mRNAs. Small RNAs bounded with effector proteins target the nucleic acids and sets of macromolecules, such as Dicer, Argonaute protein and ~21–23 nucleotide duplex-derived RNAs are recognized as main components in RNA silencing (Meister and Tuschl, 2004). While Dicer plays a role in RNA gene silencing, Dicer-1 is required for miRNA biogenesis and Dicer-2 in the siRNA pathway (Tomari and Zamore, 2005). The second core component of the effector machinery is a member of the Argonaute protein superfamily that functions in eukaryotic gene silencing, which is also present in bacterial and archaeal species. The argonaute protein superfamily can be divided into three subgroups: The Piwi clade that binds to piRNAs, the Ago clade binds to miRNAs and siRNAs, and a third clade described only in nematodes thus far (Yigit *et al.*, 2006). While it is known that the eukaryotic genes are regulated by ncRNAs, validating miRNAs from their progenitor mRNAs is needed for assigning putative function (Singh *et al.*, 2013). However, it is not so clear how RNA regulatory networks have existed with the emergence of rRNAs, tRNA, and other progenitors. Theories on their presence in earlier stages of life in archaea and bacteria have been documented (Daly *et al.*, 2013) as well as questions on how classes of ncRNAs play a role in human diseases (Esteller, 2011). The ncRNAs in bacteria serve as one of the functional elements and play an important role in gene regulation, predominantly at the post-transcription level. Primarily, they can be divided into cis-encoded and trans-encoded ncRNAs, RNA thermometers, and riboswitches, small noncoding RNAs that influence the translation and stability of mRNAs by binding to the base-pairing sites in their target transcripts. In pathogenic bacteria, numerous ncRNAs are involved in the coordinated expression of virulence determinants to facilitate the pathogenicity (Han *et al.*, 2013). With recent reports revealing that there are around 15,000 lincRNAs encoded by the human genome (Deniz and Eрман, 2017), the lincRNAs in eukaryotes have also been studied in establishing genotype–phenotype associations, which has led to advancements in prognosis, diagnosis, and treatment of human disorders.

In all living organisms, molecular machinery is activated by long double-stranded RNAs to transcribe the RNAs into short miRNAs. The miRNAs are generated from long double-stranded RNAs where they are produced by their own genes or specific part of sequences of the protein-coding genes (Yao, 2016). The biogenesis of these miRNA molecules starts with the synthesis of pri-miRNAs (Bartel, 2004; Ha and Kim, 2014; Yao, 2016). While pri-miRNAs are transcribed in the form of polycistronic transcripts, they also arise from individual transcripts constituting exonic, intergenic, or intronic sequences (Kim and Nam, 2006). Based on the location of the miRNA generation, miRNAs can be classified into two classes (Wang *et al.*, 2009): (1) intergenic miRNAs generated from transcripts of miRNA genes located inside protein-coding genes; (2) intragenic miRNAs generated from transcripts of intronic or exonic sequences of the protein-coding genes. Whereas features of ncRNAs, such as TATA box, CpG islands, TBIIF recognition, histone modifications, and initiator elements are much similar to protein-coding genes (Ozsolak *et al.*, 2008; Corcoran *et al.*, 2009), it is believed that the same regulation mechanisms of gene expression are applicable to miRNA molecules as well. RNA polymerases II and III facilitate a wide range of regulatory options and the miRNAs encoded as clusters are transcribed in the form of long polycistronic primary transcripts (Melo and Melo, 2014) or regulated autonomously (Diederichs and Haber, 2006; Yanaihara *et al.*, 2006). For example, the tumor-suppressor p53 is responsible to activate the entire miR-34 family, which plays a critical role in transactivation or repression in cell cycle mediated apoptosis (He *et al.*, 2005; Chang *et al.*, 2008). The transcription activation found in response to various growth factors such as transforming growth factor- β , platelet-derived growth factor, and bone-derived neurotrophic factor have been well studied in lieu of miRNA regulation (Corcoran *et al.*, 2009; Chan *et al.*, 2010). Further studies on epigenetics significant to miRNA gene regulation for understanding the methylation of CpG islands have shown to contribute to silence their transcription (Lujambio *et al.*, 2007, 2008; Davalos *et al.*, 2012). Specific promoters of miRNA genes are also regulated by the histone modifications process during various developmental stages and disease (Scott *et al.*, 2006).

Similarly, the three forms of lincRNAs, such as antisense lincRNAs, intronic lincRNAs and long intergenic noncoding RNAs (lincRNAs), which are the classes of lincRNAs, are spliced from multiexonic precursors (Ma *et al.*, 2013). Their role on regulation and evolutionary conservation and predicting secondary structures have been well documented (Johnsson *et al.*, 2014; Yan *et al.*, 2016). With the advent of NGS technologies, several novel lincRNAs have been identified using various approaches. How the lincRNA–protein interactions play a role in immunomodulation further taking part in the gene regulatory networks has been shown (Suravajhala *et al.*, 2015; Weikard *et al.*, 2013; Kung *et al.*, 2013). Furthermore, as lincRNAs are identified from whole transcriptome or RNA-Seq methods, interestingly a few lincRNAs have also been reported from whole exome sequencing as well (Pan *et al.*, 2016a,b). The nuclear lincRNAs in particular are known to play a major role in regulation especially serving as both *cis*- and *trans*-regulators. For example, HOTAIR, a class of lincRNAs, is well transcribed from regulatory regions and further plays a role in regulatory networks. A myriad of other ncRNAs in the form of enhancer RNAs (eRNAs) and complementary enhancer RNAs (ceRNAs) play a role in such processes. On the other hand, cytoplasmic lincRNAs are known to serve as endogenous “sponges” for miRNAs, which in turn repress miRNA repression on targeting genes (Rashid *et al.*, 2016; Thomson and Dinger, 2016). Many lincRNA–protein interactions have been shown to be associated with coactivation, repression, sequestration and organelle formation (Ferre *et al.*, 2016) while showing expression at multiple levels in the cell cycle (Paralkar and Weiss, 2013). In addition, the transposable elements (TE) have contributed widely to genome evolution and are known to play a role in maturity of noncoding transcripts (Hadjigryrou and Delihias, 2013). Conversely, the TEs playing a role in formation of ncRNAs especially lincRNA transcripts have accounted for about 30% portion of total sequences in human. While these are rarely found in protein-coding transcripts (Kapusta *et al.*, 2013), they are known to help cause signals essential for the biogenesis of many lincRNAs such as transcription initiation, splicing, or polyadenylation in human. Their role, however, in development of biomarkers has recently begun to be understood (Xi *et al.*, 2017).

Fig. 3 (a) The ncRNAs can be extracted from various specimen types such as cultured cells, model organisms, tissue and body fluids such as plasma and serum. Homogenization, laser capture microdissection (LCM), and cell sorting can be used to purify specific cell types. The ncRNA populations can be purified by gel electrophoresis and AGO2 immunoprecipitation (AGO2-IP) along with or without ultraviolet crosslinking and immunoprecipitation (CLIP). The ncRNA isolation can be done using commercially available extraction kits. miRNA quality can be assessed after using various methods that includes spectrophotometry, automated capillary electrophoresis with Bioanalyzer or Experion. (b) Applications of ncRNA profiling. Abbreviations: qPCR, quantitative PCR; RNA-Seq, RNA sequencing. Image conceptualized from Pritchard *et al.*, 2012. *MicroRNA profiling: approaches and considerations*. *Nature Reviews Genetics* 13, 358–369.

Comparing the ncRNA profiles between different stages of development has facilitated in developmental transitions or cellular differentiation. Whole transcriptome or RNA sequencing (RNA-Seq) is an important approach for both identifying and profiling of novel ncRNAs. The miRNAs linked with mRNA or with RNA-binding protein can be analyzed using crosslinking immunoprecipitation (CLIP) using ultraviolet rays to create covalent bonds between RNA-binding proteins and RNA (Fig. 3).

Table 1 A gist of ncRNA databases and tools along with their association with other small molecules

Type	Database name	Function	Strengths	Weaknesses, if any	Reference	URL
Micro RNA databases	miRBASE	Database of published miRNA sequences and annotation	User-friendly with good number of options for analyzing the miRNA. A new option to identify the novel miRNAs	miRNA-miRNA interactions cannot be ascertained completely	Griffiths-Jones <i>et al.</i> (2006)	http://www.mirbase.org/
	miRwalk	Database on predicted and validated microRNA targets	A whole set of miRNA targets including pathway information is made accessible through this. A comprehensive list of targets including other ncRNAs is detailed. Users have the flexibility to study any custom miRNAs or target genes of interest, related to functional miRNA annotations	Targeted regions are many. A careful double check is required to analyze them, Not so user-friendly	Dweep <i>et al.</i> (2011)	http://zmf.umm.uni-heidelberg.de/apps/zmf/mirwalk/
	miRDB	MicroRNA target prediction and functional study database	Users have the flexibility to study any custom miRNAs or target genes of interest, related to functional miRNA annotations	–	Wong and Wang (2015)	http://www.mirdb.org/
	miRTarBase	Experimentally validated microRNA-target interactions database	Comprehensively annotated, experimentally validated miRNA-target interactions database		Hsu <i>et al.</i> (2011)	http://mirtarbase.mbc.nctu.edu.tw/
	VirMIRDB	Predicts viral microRNA candidate hairpins	Beneficial for viral miRNAs and host-gene interaction studies	Not so user-friendly, Execution of the entire bioinformatics' pipeline is tough to scan for putative miRNA hairpins	Li <i>et al.</i> (2008)	http://alk.ibms.sinica.edu.tw/cgi-bin/miRNA/miRNA.cgi
LncRNA-protein interaction databases	NONCODE	An integrated knowledge database dedicated to ncRNAs, especially lncRNAs	Provides both basic and advance information about LncRNA such expression profile, conservation info, predicted function and disease relation	Does not give information about tRNAs and rRNAs	Zhao <i>et al.</i> (2016)	http://www.noncode.org/
	LncRNAwiki	Community-curated lncRNA knowledgebase	Integrates information on human lncRNAs from multiple different resources	Relies on community intelligence to curate a wide range of lncRNA-related topic, improvement is needed to link with other existing relevant databases	Ma <i>et al.</i> (2015)	http://lncrna.big.ac.cn/index.php/Main_Page
	LncRNAdb	The reference database for functional long noncoding RNAs	User-friendly and thoroughly compiled and updated information of lncRNAs in a variety of systems	Limited to the location of lncRNA only	Amaral <i>et al.</i> (2011)	http://www.lncrnadb.org/
LncRNA-protein interaction prediction databases	Interaction Pattern (IP) Miner	Predicts ncRNA-protein interactions from protein sequences	Good performance for mining the ncRNA-protein interactions	Bash/command line tools and applicable for commandline user interface (GUI). Uses Python scripts	Pan <i>et al.</i> (2016a, b)	http://www.csbio.sjtu.edu.cn/bioinf/IPMiner/IPMiner.tar.gz

(Continued)

Table 1 Continued

Type	Database name	Function	Strengths	Weaknesses, if any	Reference	URL
Binding site databases	IncPro	Predicts the interaction between long noncoding RNAs and proteins	Computational friendly	Interaction data is still considered unsatisfactory because of the large number of proteins. <i>Bona fide</i> ity is at risk	Lu <i>et al.</i> (2013)	http://bioinfo.bjmu.edu.cn/incpro/
	ncRNAs and protein related bio macromolecules interaction database	Integrates experimentally verified functional interactions between noncoding RNAs and other biomolecules (proteins, RNAs and genomic DNAs)	Novel integrated functional interactions between ncRNAs and protein related macromolecules (PRM) into a single, easily accessible database	Interactions are manually collected from publication, however, they are curated	Wu <i>et al.</i> (2006)	http://www.bioinfo.org/NP/Inter
	RNA-protein Association and Interaction Networks	A database of ncRNA-RNA and ncRNA-protein interactions	Integrated with the STRING database	Does not give information about RNA-protein binding site integration	Junge <i>et al.</i> (2017)	https://rth.dk/resources/rain/
	Protein-RNA interaction prediction	Predicts structural fragments information of given protein and RNA	User-friendly with support-vector machine-based method. Predicts protein-RNA interaction pairs, based on both the sequences and structures	Does not give information and determines the binding partners for other types of proteins which are able to interact with both DNA and RNA	Suresh <i>et al.</i> (2015)	http://ctsb.is.wfubmc.edu/projects/rpi-pred
	RNA-associated interaction database	Predicts RNA-associated (RNA-Protein/RNA-RNA) interactions	Users can query, browse, analyze, and manipulate RNA-associated (RNA-RNA/RNA-protein) interaction		Zhang <i>et al.</i> (2014)	http://www.rna-society.org/raid/
	Protein-RNA Interface Database (PRIDB)	Database of RNA-Protein interfaces	It displays interfacial amino acids and ribonucleotides within the primary sequences of the interacting protein and RNA chains. PRIDB also identifies ProSite motifs in protein chains and FR3D motifs in RNA chains and provides links to external databases	Highly reliant on Java. Interfaces in the RNA-protein complexes can be visualized using an integrated JMol applet or downloaded in a machine-readable format	Lewis <i>et al.</i> (2011)	http://bindr.gdcb.iastate.edu/PRIDB
Bacteria	RNA-Binding Protein Database (RBPDB)	Repository of experimental observation of RNA-binding sites	Freely accessible by a web interface. Can also use to scan sequences for RBP-binding sites	Currently populated only with data from metazoans	Cook <i>et al.</i> (2011)	http://rbpdb.ccbr.utoronto.ca
	RsiteDB	Describes, classifies and predicts the interactions between RNA and protein binding pockets	Provides information about the protein binding pockets that interact with single-stranded RNA nucleotide bases	Uses Java to visualize the results through Java applets	Shulman-Peleg <i>et al.</i> (2009)	http://bioinfo3d.cs.tau.ac.il/RsiteDB
	NOCO RNAc	A Java based tool for the prediction and characterization of ncRNA transcripts in bacteria	Characterizes noncoding RNAs in prokaryotes. Gives genome-wide prediction of ncRNA transcripts in bacteria	Does not predict, for example, 23S ribosomal RNA	Herbig and Nieselt (2011)	http://www.swmath.org/software/17423

RNA sequences bound by a protein of interest are then detected by high-throughput sequencing in combination with HITS-CLIP or photoactivatable ribonucleoside-enhanced CLIP (PAR-CLIP) using photoreactive analogs. Integrative analyses of miRNAs and lncRNAs are done *in silico* using MAGIA95 and mirConnX96, Cytoscape, a network visualization tool, as well as with other databases such as miRbase, lncRNAdb, and NONCODE (see [Table 1](#)). Such profiling has enabled study of miRNAs as biomarkers for a wide variety of diseases such as cancer, autoimmune, psychiatric, and neurological disorders. While it has been applied successfully for the cancer classification of unknown origin, various clinical diagnostic assays those including specific cancer-derived miRNAs and different body fluids have been characterized ([Pritchard et al., 2012](#)). In profiling lncRNAs, they can be functionally impaired by blocking their molecular interactions by applying small molecule inhibitors that mask the binding sites and further help in diagnosis of diseases ([Sanchez and Huarte, 2013](#)). For example, preventing the interaction of HOTAIR with the PRC2 or LSD1 complexes using small molecular inhibitors may limit the metastatic potential of breast cancers ([Tsai et al., 2011](#)). In this process, oligonucleotides have also been used to target a specific ncRNA region and block its correct folding ([Colley and Leedman, 2009](#)).

Illustrative Example

The role of ncRNAs in various diseases, especially cancers, has been well documented ([Esteller, 2011](#)) with less focus on stem cells. The cancer stem cells (CSC) are a small subset of cancer cells that are associated with normal stem cells and are responsible for drug/treatment resistance, tumor recurrence, and metastasis ([Garg, 2015](#)). While they were recognized few years ago, their identification and characterization have already been done continuously for 15 years in some malignancies, such as leukemia and other tumors ([Bonnet and Dick, 1997](#)). Due to self-renewal and tumor generation capacity, CSCs have become potential targets for various cancer treatments including prostate, breast, colon, head and neck, colorectal, and brain ([Huang and Rofstad, 2017](#)). It has been reported that miRNAs play a vital role in the regulation of CSCs in various types of malignant tumors at the posttranscriptional level ([Ali et al., 2013](#)) while it is widely accepted that CSCs play a significant role in cell biology of cancers. Further, they are known to work via signaling pathways that mediate the expression through self-renewal, such as Notch and Wnt ([Prokopi et al., 2015](#)). In several studies many miRNAs showed different expression profiles in the various types of cancer ([Ma et al., 2015](#)) and their role as potential targets for cancer therapy is widely known ([Fig. 4](#)) ([Bimonte et al., 2016](#)). Based on their important roles in progression of human cancer and expression profile miRNAs are classified into two groups: (1) oncogenic miRNAs, which are reported to upregulate in tumor cells ([Bao et al., 2011](#); [Albulescu et al., 2011](#)); (2) tumor suppressor miRNAs, which are reported to be downregulated in pancreatic cancer ([Ji et al., 2009](#); [Haselmann et al., 2014](#)). Reports on downregulation of brain specific neuromiR-124 in glioblastoma has shown to improve the number of CSCs and oncogenic capacity ([Bian and Sun, 2011](#)) and let-7 downregulation in lung cancer linked with poor survival ([Calin and Croce, 2006](#)). Likewise, pneumomiR-29, a lung specific miRNA, is shown to suppress the tumorigenicity in non-small cell lung cancer cells while two other, such as miR-143 and miR-145, have been reported to be downregulated in

Fig. 4 The miRNAs targeted to various major cancer types.

various cancers including breast, cervical, and colorectal (Prokopi *et al.*, 2015). Despite these results, more studies on the function of ncRNAs in biology of CSCs will be needed in the future in order to discover novel oncology therapeutics (Parasramka *et al.*, 2016).

Technological developments enabled us to get volumes of data using the high-throughput NGS technologies. Evidence suggests that large amount of transcripts especially miRNAs have been modeled (Friedlander *et al.*, 2008; Lu *et al.*, 2009). The first reports on analyzing the RNA data to search new ncRNA gene sequences and predicting their targets came in the year 2003 (Lim *et al.*, 2003). While computational modeling was employed to use precursors as input and functional end products as ncRNAs, previous approaches used finding new miRNAs based on sequence data (Mendes *et al.*, 2009). Xie *et al.* (2005) reported artificial intelligence using learning algorithms used with sets of test known data and targets are predicted. Since then, many new ncRNA annotations were reported and put in use for the public domain. With high-throughput deep sequencing creating much more roadmaps for the ncRNA discovery (Lu *et al.*, 2005), hairpin structures are used to mimic miRNA byproducts (Friedlander *et al.*, 2008) and least-square classification algorithm for miRNAs (Lu *et al.*, 2009). While earlier methods were used to predict ncRNAs understanding ncRNA biogenesis and target specificity, HITS approaches involving bioinformatics simulations/predictions are needed. Even though constraints in using sequence data would be hard to predict ncRNA computationally, complex diseases affected by a number of ncRNAs rather than a single ncRNAs have been documented (Kargul and Laurent, 2011). Characterizing transcript structures and understanding expression profiles mediating regulatory roles are in agreement with good number of databases and repositories documented for ncRNAs (Table 1). Nevertheless, with big data revolution enabling us to handle huge exponential volume of ncRNA data, developing robust mathematical models for prediction of ncRNAs would be beneficial to the research community.

Future Directions

The list of ncRNAs in the genomes has consistently grown without worthy annotation with many of them associated with diseases. Although the role of ncRNAs towards their regulation in important diseases, such as cancer, obesity, immunomodulatory diseases etc. are well reported, the larger diversity of their function, explosive growth in the known functional relationships between ncRNAs and diseases such as cancer can be categorically approached. These can be characterized based on in silico predictions carried out in the laboratory keeping in view of the following documentation:

- (1) While finding ncRNAs linked to immunomodulatory disease types, finding the various interaction partners of ncRNAs especially those that can affect protein function and localization needs to be attempted. As far as computational methods to the problem are concerned, this focus could not only allow us to process such data but also ensure we build a healthy community annotated wiki catalog of ncRNAs. This resource can serve for wet-lab validation or develop a machine learning intensive web server in predicting the interactions among the unknown ncRNA–protein pairs.
- (2) Could we expect to find ncRNAs to control protein complexes, for example whether or not any specific targets are involved in this process leading to immunomodulation. With the larger diversity of function of ncRNAs, explosive growth in functional relationships of ncRNAs and proteins causal to diseases would be categorically approached. We expect that a majority of ncRNAs might be the direct descendants from the known unknown regions or the domains of unknown function, which possibly would provide clues on ncRNAs binding to disordered regions of the proteins. If it were the case, the bound residues intrinsic to the immunomodulated state can be targeted for downstream experiments in the laboratory to identify prognostic biomarkers.
- (3) Identifying regulatory elements associated with a disease and validating them post exome sequencing using Sanger sequencing has been a routine task. In this process, distinct signatures are discovered among various populations across disease spectrum. What remains as a challenge is to identify those that are most previously uncharacterized and find if they are specific to population. Notable among such identified mutations or variants could be the one that pops up from ncRNAs where these mutation hotspots are seen. If by the advent of sequencing chemistry going wrong, a study defining exome mutational spectrum would highlight discovery of ncRNA mutations playing an important role in therapeutic targets.
- (4) Can CRISPR/Cas9 delete a ncRNA gene? Can these be used as targets for them, for example lncRNAs? As lncRNAs make an effect on its neighboring genes, it would be interesting to see the mutations from these genes that are associated with it. If they modulate the expression, that would be an interesting case to further explore which will allow lncRNA sequences to serve as protospacer adjacent motifs in the genome. Additionally, molecular causes especially studying regulatory interactions between classes of ncRNAs and proteins would have a significant influence on the organism and diseases remains a challenge. A hope that the NGS technologies have an answer subtly proves this.

Acknowledgments

PS thanks Asif Khan and Shobha Ranganathan for inviting us to write a book article.

Authors' contributions

PT, SG, and PS wrote the entire initial draft with AK and MS focusing on miRNAs and diseases. SM, SLK, BM, and KM wrote the parts on regulation and biogenesis of ncRNAs, and VSS on big data challenges. PS proofread the manuscript. All authors read and approved the book article.

Introduction

The development of biomarker discovery has revolutionized the field of disease diagnosis and prognosis. Bioinformatics based approaches for biomarker identification are growing with the advances in genome sequencing resulting in a huge amount of sequences. Various bioinformatics based techniques, such as machine learning, network-based approach, and text-mining for identification and characterization of biomarkers are widely in use (Cohen and Hersh, 2005). As per the World Health Organization, biomarkers reflect an interaction between a biological system and a potential hazard, which may be chemical, physical, or biological (WHO International Programme on Chemical Safety Biomarkers and Risk Assessment: Concepts and Principles, 1993). While biomarkers can help in the care of patients with disease or no disease, on the basis of this clinical perspective, biomarkers are classified into prognostic, diagnostic, predictive and therapeutic (Carlomagno *et al.*, 2017). Prediction of disease is not the only application of biomarkers but it helps in monitoring toxicity for the development and discovery of new drugs. With bioinformatics applications important in filling this gap between bioanalytics and initial discovery phase, semantic searches and biomedical literature by and large have allowed us to efficiently identify and characterize biomarkers (Bundschus *et al.*, 2008). The main focus of this review is to provide information on extraction and identification of biomarker information.

Exploring Contextual Genes

A complex cellular system of higher organisms consists of huge number of processes running simultaneously. Maintaining a particular cellular state is one of the major tasks regulated synchronously in a cell. Transition of cellular state from one state to another requires the alterations in regulatory pathways as well, which consists of a large number of genes functioning to get a particular state. Such genes with functional relatedness are called contextual genes (Ferrer *et al.*, 2010). Genome context methods were used to predict this functional relatedness between genes using the patterns of existence and relative locations of the homologs. While annotating functional and structural information of genes in newly sequenced genomes, homology is used a reliable tool; we also explore contextual genes in targeted genomes to find out their functional relatedness. Widely used context methods in literature are phylogenetic profiles, gene neighbor, gene cluster, and gene fusion (Fig. 1) (Ferrer *et al.*, 2010). The important criteria for these methods are presence of homologous sequences for the genes in the target genome where in this case the degree of sequence similarity is checked. The contextual gene methods are classified by and large into (1) full coverage and (2) restricted coverage with the former generating scores for all possible gene pairs from a genome, while the other essentially generates scores only for some pairs. One widely employed full coverage method is the phylogenetic profile (Fig. 1) and gene neighbor methods (Fig. 1), which are used to compare sequences based on the degree of full coverage, whereas the gene cluster and the gene fusion are a part of restricted coverage methods (Fig. 1). However, the contexts used to infer functional relationships between genes with or without sequence similarity based on evolutionary relationships can be biased in some cases (Krawczuk and Łukaszuk, 2016). To check this, crude statistics and normalization are done to enhance the performance and genome dependence (Lehmann and Romano, 2005). In addition, combining scores from two different methods, machine learning and classification with parameter selection and tuning, would help achieve better results. Among these methods, the gene neighbor methods are known to outperform the phylogenetic profile method by as much as 40% in sensitivity when compared with the gene cluster method at low sensitivities.

Methods Used for Biomarker Identification

Identifying biomarkers is one of the greatest challenges as different genotype–phenotype correlation from large-scale biological data is assessed. There are a good number of text mining, knowledge-based and network-based methods to discover biomarkers from literature (Hall and Holmes, 2003). These can be better made by constructing a resource based on indexed text or dictionary used from a finite state machine. One of the key components of identifying contextual genes is condition-specific interactions in biological networks. Valuable mechanistic insights can be derived from functional analyses of genomic data. A list of commonly used data mining methods is given below.

- Unpaired null hypothesis testing: This is a univariate filter method where the calculated probability (P -value) serves as the evaluation measure to rate variables on their discriminatory ability (Lehmann and Romano, 2005).
- Principal component analysis: This technique is an unsupervised projection method, which employs linear combinations of variables based on the variance of the original data (Ringnér, 2008).

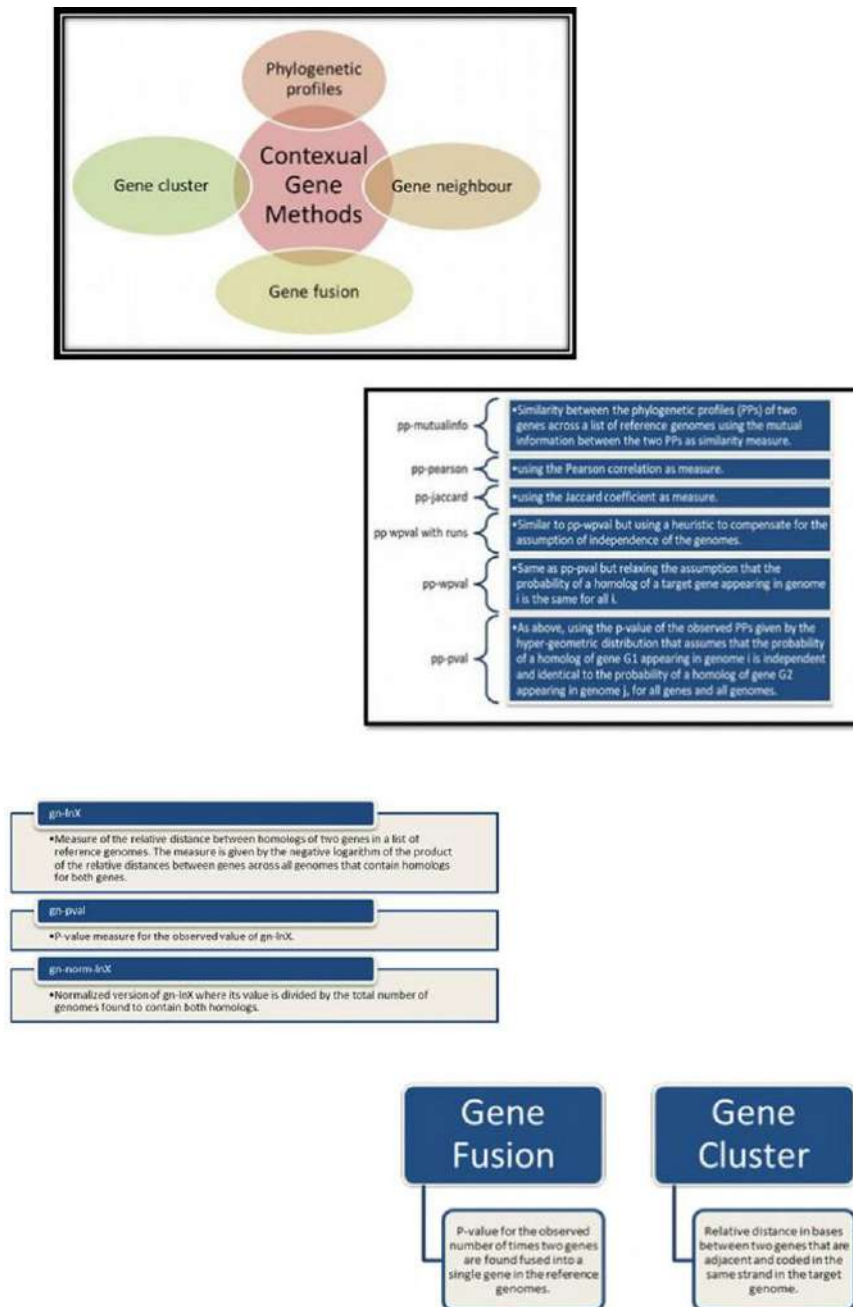

Fig. 1 Widely used context methods. (a) Contextual gene methods and their classification, (b) an overview of phylogenetic profiles methods, (c) gene neighbor methods and (d) gene fusion and cluster methods.

- Information gain: Is another univariate filter method, which evaluates entropy reduction of data due to feature separation (Hall and Holmes, 2003).
- ReliefF (RF): This is a multivariate filtration method, in which the RF score relies on the concept that values of a significant feature are correlated with the feature values of an instance of the same class and uncorrelated with the feature values of an instance of the other class (Robnik-Sikonja, 2016).
- Associative voting: This is another multivariate filter method and uses a rule-based evaluation criterion by a special form of association rules; considers interaction among features (Osl et al., 2008).
- Unpaired biomarker identifier: Is a univariate filter method, in which a statistical score can be determined by combining a discriminant measure with a biological effect term appropriate for binary classifications alone (Baumgartner et al., 2010).
- Support vector machine recursive feature elimination is an embedded selection method that optimizes the weights of SVM classifiers to rank features (Guyon et al., 2002).

- Random forest models is an embedded selection method, using bagging and random subspace methods to construct a collection of decision trees to identify a complete set of significant features (Enot *et al.*, 2006).
- Aggregating feature selection is an ensemble selection method that aggregates multiple feature selection results to a consensus ranking (Saeys *et al.*, 2008).
- Stacked feature ranking is an ensemble selection method that has stacked learning architecture to construct a consensus feature ranking by combining multiple feature selection methods (Netzer *et al.*, 2009).
- Wrapper approach evaluates the merit of a feature subset by accuracy estimates using a classifier and produces a subset of very few features that are dominated by stronger and uncorrelated attributes (Hall and Holmes, 2003). There are a few guilt-by-association studies to check these features (Shin *et al.*, 2008).
- Paired null hypothesis testing is a univariate filter method where *P*-value serves as evaluation measure for the discriminatory ability of variables (Lehmann and Romano, 2005).
- Paired biomarker identifier is an univariate filter method that uses a statistical evaluation score by combining biological effects (Baumgartner *et al.*, 2010) (Fig. 2).

Other Feature Selection Methods

Next-generation sequencing has given us tremendous impetus in identifying the biomarkers and with the help of feature selection/classification methods, there arose an interest to discern them using deep learning approaches (Lee *et al.*, 2018). Several combinatorial based methods are known for identification of biomarkers, for example heuristic searches, hybrid methods, and exhaustive methods, which have been reviewed (Wang *et al.*, 2016). There is still apaucity of resources employing these features. For example, a database of mutation-gene-drug relations for such classification features could prove to be a valuable resource for researchers interested in personalized medicine and genealogy (Wu *et al.*, 2014). For example, Wu *et al.* (2014) have developed a large-scale text-mining system to generate molecular profiles of thyroid cancer using literature based classification scoring schemes. In this process, they are able to identify key genes and pathways for easy prioritizing diagnostic biomarkers for therapeutic use. Similarly, Li *et al.* (2014) prioritized cancer-related miRNAs using network-based approaches by employing the random-walk algorithm to elucidate miRNA-disease networks. In the recent past knowledge-driven text-mining approaches have shown tremendous applications for extracting biomarker information covering all therapeutic areas (Bravo *et al.*, 2014). These are preferentially used by taking Medline publications containing the MeSH terms and other bibliometric analysis. Automated extraction of biomarkers using semantic graphs has also been attempted recently (Vlietstra *et al.*, 2017). Within the last few years, systems biology approaches clubbed with NGS became more amenable in extracting the useful information (Mayer *et al.*, 2012), biomarker identification and computationally expensive and challenging task methods such as knowledge graphs prove to be very useful in bringing exponential growth of biomedical literature and databases (Bravo *et al.*, 2014).

Structured knowledge is better represented in the form of a knowledge graph where unique relationships are defined using the Unified Medical Language System (UMLS), which integrates relationships extracted from Medline abstracts (Bodenreider, 2004). The knowledge graph runs on a 1.8.3 Neo4j graph database, the 3,527,423 biomedical concepts are represented as vertices, with 68,413,238 relationships between them. The individual concepts represent units of thought, which are atomic and unique. Two concepts can be connected to each other with one or more semantic relationships (also referred to as predicates), such as “causes” or “inhibits,” thereby forming a triple. In addition, ranking and filtering methods are applied by checking recall, precision, and cumulative gains. The list of potential biomarker compounds generated by the method could be retrieved by the aforementioned processes and later assigned to the error categories. This will also allow us to recognize and apply normalization methods for the disease and biomarker entities in biomedical publications by means of the biomedical named entity recognition system. A gene dictionary constituting a huge collection of terms referring to human genes and proteins is integrated with data from three biological databases. This is complemented by a disease dictionary with UMLS metathesaurus (UMLS Methathesaurus, 2018), a large, multipurpose, and multilingual thesaurus that contains millions of biomedical and health-related concepts, their synonymous names, and their known relationships. Both dictionaries are curated and extended semiautomatically using different rules to facilitate the matching task.

Methodology focused on the extraction of disease–biomarker associations reported in the literature is not just limited to the methods as mentioned above but a knowledge-driven approach takes advantage of the annotation of MEDLINE publications pertaining to biomarkers with MeSH terms, narrowing the search for specific publications and therefore minimizing the false positive ratio. The application of this methodology is shown using a neural network-based biomarker association extraction approach for cancer classification (Bravo *et al.*, 2014; Kim *et al.*, 2007). These are complemented by a linear biomarker association network (LN), a fully connected neural network algorithm that assumes that the expression level of a biomarker is associated with some other biomarkers and can be estimated using a linear combination. This is briefly described below.

Consider a set of p biomarkers. The input of the LN represents the observed levels of the p biomarkers, denoted as $x = [x_1, x_2, \dots, x_p]^T$, and the output represents the corresponding estimated results, denoted as $y = [y_1, y_2, \dots, y_p]^T$. Let $A = \{a_{ij} \in \mathbb{R}, a_{ii} = 0; i, j = 1, 2, \dots, p\}$ denotes the connection matrix of the network, the operation of the LN can be represented as follows:

$$y = Ax + B, \quad B = [b_1, b_2, \dots, b_p]^T$$

where $b_i, i = 1, 2, \dots, p$, represents the expression baseline of the i th biomarker.

Fig. 2 An overview of context mining process flow. The experimental data is measured from contextual information, before annotations are drawn from various methods.

The classification features using conventional methods include Fisher discriminant analysis, k -nearest neighborhood, Bayesian network classifier (BN), and support vector machines with both linear kernels (linear-SVM) and radial basis function kernels (rbf-SVM). Among these conventional methods, the BN classifier, linear-SVM, and RBF-SVM require their parameters to be tuned for best performance. Wang *et al.* (2018) have developed a new cancer classification approach based on the concept of a biomarker association network (BAN) and a neural network structure to model the biomarker association patterns responsible for cancer. Using publicly available datasets it has been shown that the BAN-based classification approaches, in particular, the NLN classifier, achieve excellent classification performances on the four datasets (Wang *et al.*, 2018). On the other hand, extracting semantic biomedical relations with a sequence labeling approach based on conditional random fields is studied with general free text searchers containing concise phrases. However, these are bound by limitations because an effective search using gene cards and other secondary repesitive database searchers are necessitated to study them (Wang *et al.*, 2009).

Conclusions

We have presented an overview of extraction and identification of biomarker information using different methods, primarily based on feature selection, knowledge-derived methods, and graphs. Identification of biomarkers not only serves as a distinct identity for understanding molecular, physiological, and structural variations but also helps disseminate a contextual flow for future methods in accurately classifying the biomarkers. An integrated embedded approach to identify biomarkers through graph theories, biological networking, and modeled through learning algorithms would be of much use to the research community. There is a vivid hope that classification feature selection methods through machine learning approaches would bring identification of the biomarkers more accurately.

Introduction

Since its emergence in the mid-1990s, Systems Biology has laid the foundations for developing systems level understanding of living systems beyond the paradigms of single gene/protein/molecular view of biology (Kitano, 2002a,b; Ideker *et al.*, 2001). With the rapid development of large scale omics experimental systems in tandem with computational tools for molecular pathway visualization, modeling, data management and analysis, the field has contributed to deeper understanding of fundamental mechanisms of biological processes as well as their applications in various branches of medicine and biotechnology (Tyson *et al.*, 2001; Novak and Tyson, 1993; Chen *et al.*, 2004; Aoki *et al.*, 2011; Schoeberl *et al.*, 2010, 2009).

Particularly, modeling and simulation efforts have been applied in early approaches to study cell cycle dynamics (Tyson *et al.*, 2001; Novak and Tyson, 1993; Chen *et al.*, 2004) and in analysis of signaling pathways implicated in cancer, for example, the mitogen-activated protein kinase (MAPK) dynamics (Aoki *et al.*, 2011). Such modeling efforts have also found application in drug discovery and clinical trial designs as demonstrated by the development of MM-121 an ErbB3 antibody as an investigational drug candidate for various cancer sub-types (e.g., heregulin positive Non-small cell lung cancer) (Schoeberl *et al.*, 2010, 2009).

Further, approaches from systems biology have been integrated with traditional pharmacodynamics/pharmacokinetic (PKPD) and ADME-Tox (drug administration, distribution, metabolism and excretion and toxicology) modeling techniques to develop novel analysis pipelines in systems toxicology as reviewed in (Ghosh *et al.*, 2013b). Particularly, multiple spatio-temporal modeling efforts have been developed as part of the High Definition (HD) Physiology project in Japan and the Virtual Physiological Human (VPH) project in Europe (Ghosh *et al.*, 2013b). In recent years, systems approach to the study of chemical toxicology have gained increasing attention with the restriction on animal testing for toxicity studies in various industries like cosmetics and food. Concurrently, new analytical constructs, like the Adverse Outcome Pathways (AOP) have been mandated by the OECD which “...describe sequential chain of causally linked events at different levels of biological organization that lead to an adverse health or ecotoxicological effect” (see “Relevant Websites section”). Various *in silico* pipelines are been developed for multiscale modeling of safety assessments based on *in vitro* studies as well as toxicogenomics data on chemical compound screens (Bois *et al.*, 2017; Vinken, 2015).

While hypothesis-driven modeling approaches have yielded practical applications of systems biology as noted above, data-driven techniques are gaining traction in recent years (Webb, 2018). Wide-ranging applications of deep learning models have been developed in cheminformatics, translational biomarker and drug discovery and clinical applications (comprehensive reference available at (Webb, 2018)). Particularly, success of such deep architecture models has been demonstrated in genomics field including the DeepVariant model for variant calling, enhancer predictions, and population genomics (Poplin *et al.*, 2017). With the ability to generate omics scale data at various biological layers (transcriptomics, proteomics, metabolomics), novel analytics and data management are being developed for obtaining systems level insights from multi-omics data (Yi *et al.*, 2014; Shehzad *et al.*, 2014; Imam *et al.*, 2015; Schulz *et al.*, 2014; Yugi *et al.*, 2016). Specifically, *Trans-Omics* approach has been proposed such as in (Yugi *et al.*, 2016) to reconstruct biochemical and regulatory networks across multiple layers of data.

Such methods which bridge multiple dimensions of data and analysis/modeling approaches herald a new direction for systems biology. Specifically, with the advent of *big data* in biology together with the rapid pace of development of machine learning (ML)/artificial intelligence (AI), it is increasing evident that new horizons need to be explored to leverage systems level approaches on a broader scale spanning basic biology, drug discovery to translational and clinical applications and moving to patient reported phenotypic data, as shown schematically in Fig. 1.

In this article, to overview the new horizons in systems biology-guided approaches in biology and medicine, we identify the digital drivers shaping the current landscape and explore the need for next generation platforms to connect the drivers. Some case studies of connecting multi-dimensional data and analysis for different workflows are also discussed. We then conclude with perspectives on the vision driving next-generation research in biology and healthcare.

Digital Drivers at the Intersection of Technology and Medicine

This section outlines some of the digital drivers which are playing a pivotal role in the changing landscape of systems biology and its applications in biology and medicine. Highlighting the key areas as identified in (Hird *et al.*, 2016), the section captures impact of the digital drivers before presenting the role of potential new approaches in the next section.

Role of Data

With increasing volumes of data been generated in multiple dimensions, the role of data is becoming center stage in biology and medicine. High-throughput biotechnologies including DNA sequencing, transcriptomics, proteomics and metabolomics comprise

Fig. 1 New Horizons of data and analytics in biology and medicine. Multiple dimensions of data are being generated in the new era of medicine having distinct features- from genomics and molecular data to clinical and life-style phenotypes); such high dimensional (HD) data needs connection to novel HD analytics with different analytics techniques to obtain insights at different scales. Reproduced from Hird, N., Ghosh, S., Kitano, H., 2016. Digital health revolution: Perfect storm or perfect opportunity for pharmaceutical R&D? Drug Discovery Today. Available at: <http://doi.org/10.1016/j.drudis.2016.01.010>.

"Big data", characterized by the 4 'V's – data having high Volume, Variety, Velocity and Variability, are being generated in next generation experimental systems at the levels of single cells, tissues, organs to individuals. The most prevalent data at individual level is genotype, and genotype-phenotype correlations. A number of systems biology approaches have emerged to fill the gap between genotype and phenotype with the use of molecular big data such as protein-protein interaction network (Ben-Hamo and Efroni, 2013). On the other hand, a variety of "Small data" for each individual is being collected by multiple digital sources in hospital (Hood and Stephen, 2011) as well as home settings, such as personalized and time or event-dependent physiological parameters, social network and patterns in behavior and its geographical areas.

The integration of the multi-level, multi-scope and multi-scale data has given rise to the concepts of "extended phenotype" (Jain *et al.*, 2015). Such a paradigm shift in data in systems biology will enable to assess the open question how the phenotype is generated from the genotype, bringing the most important 'V' of Value to data.

Role of Devices

Another key driver in digital technologies is the rapid evolution in computers, sensors, and robotics, both in power and performance. Wearable devices with embedded sensors for measuring vital signs, to telemedicine devices and robotic automation of large scale laboratory experiments are now being developed. Moreover, together with the progress in Information and Communication Technologies (ICT) like the internet ubiquity, high network intensity and substantial data security, these hardware devices can be connected with smart devices such as wearable monitors, smart watches, cell phones or even household electrical appliances, generally defined under the umbrella term of Internet of Things (IoT). In the sense of extended phenotype, these "off the shelf" technologies bring about a transition from the world of a collection of scattered small data to a new future of integrated big data – enabling specialists from diverse domains, such as biologists and data analysts to access and analyze the data from different perspectives.

Role of Advanced Analytics and Machine Intelligence

The flood of data coming from multiple device source far exceeds the cognitive threshold of researchers. The development of advanced analytics techniques for such High-dimension (HD) data is ranging from inference techniques (Schadt *et al.*, 2005) to so-called Machine Intelligence (Chouard and Venema, 2015) including the methodologies of machine learning and artificial intelligence (AI). These techniques provide powerful predictions to identify patterns in the data and insights for deep phenotyping of the target systems. For example, the community challenges of applying machine learning techniques in inference of gene regulatory network (GRN) have established community-based methodologies as a powerful approach to predict GRN from accumulative transcriptome data (Marbach *et al.*, 2012). Genome-wide association studies (GWAS)-guided or targeted metabolomics technology-driven weighted co-expression network analysis (WGCNA) of HD transcriptome data have provided insights on

potential therapeutic strategy for this subset of breast cancer and the potential etiology of psychiatric disorders, respectively (O'Dushlaine *et al.*, 2015; Camarda *et al.*, 2016). Recent studies in healthcare have applied these techniques such as for disease biomarkers identification, drug discovery and trend analysis in disease spread (Ginsberg *et al.*, 2009; Libbrecht and Noble, 2015).

Role of Platforms

These key trends are opening up new challenges and opportunities in systems biology for solving systems complexity represented in data and approaches. The application of systems biology in domains such as systems drug design or personalized medicine requires sophisticated data-handling tools, modeling, integrated computational analysis and knowledge aggregation in a connected manner, as presented in Fig. 2. On the other hand, every workflow in systems biology must be specialized to the target system and the problem. In reality, researchers are collecting and connecting data and tools for each building block in each workflow in an ad-hoc manner. Also, as no single method/data universally applicable to all workflows, the choice of whether and how to utilize them will rely on individual researchers' ability and accessibility.

Under these circumstances, an integrated platform is required where researchers can find the right data and suitable tools and devices, build the problem-specific workflow, and execute the entire workflow. Several efforts have begun to develop such integrated platforms in the domain of systems biology, healthcare and beyond (Table 1). For example, Galaxy has involved several bioinformatics researchers to build a robust and reusable data analytic pipelines around next-generation sequencing (NGS) data (Goecks *et al.*, 2010). Genome-space (Qu *et al.*, 2016) involves another established analytic platform such as Gene Pattern (Reich *et al.*, 2006) and geWorkBench5 (Floratos *et al.*, 2010), which is also focusing on NGS data analytics. Another effort in this direction is the Garuda Platform (Ghosh *et al.*, 2011), a connectivity and automation platform which aims to provide a gateway of tools (called gadgets in Garuda) on different domains and dynamic construction of workflows (called Garuda recipes) by discovering and connecting different gadgets in a system agnostic manner (web-based applications and standalone software). Garuda is built as a light-weight programming language independent framework which allows seamless connection of software, devices in a social community network (called gadget graphs).

Role of Community – Human in the Loop Research

Finally, we identify and discuss on the critical role of as a key driver in digital technologies-driven systems biology and its applications. It is becoming increasingly apparent that for large-scale projects which involve massive amounts of data, diverse ICT needs and analytics techniques, cross and inter-disciplinary skills are the need of the future – it is impossible for a single researcher or even a single laboratory to harness all the different dimensions of a research project.

Community-driven data collection through data repositories has grown in its popularity and necessity, especially for the omics data (Perez-Riverol *et al.*, 2017), while the application of mass spectrometry analysis such as metabolomics and proteomics have certain difficulties to standardize the needs and usability with regards to the type of data and analysis (Kind *et al.*, 2009; Wang *et al.*, 2016). Apart from the data, notably, the concept of Wisdom of Crowd, where the collective knowledge of a community is greater than the knowledge of any individual, has become proven in both network inference of living organisms (Marbach *et al.*, 2012). Under these circumstances, consistency and the interoperability of various algorithms, tools and devices are the first step towards the goal.

Fig. 2 Digital drivers at the intersection of technology and medicine. Various dimensions of big data, novel high-throughput experimental technologies, smart devices coupled with rapid development in ML/AI is driving the frontiers of computational systems biology and its application; such digital drivers highlight the need of next generation connected platforms to leverage the multi-dimensional drivers. The standardization of the software, i.e., a common language for inter-operability, is the key to store and share information in a seamless and unambiguous fashion. One successful case is The Systems Biology Markup Language (SBML: see “Relevant Websites section”), which is set of standardization for mathematical modeling and simulation executable through various modeling and simulation software in systems biology. Importantly, the SBML community was evolved to structure themselves and keeps growing themselves to engage, reach out and educate the scientific community. Over 200 modeling and simulation software in biology domain comply with SBML enabling the community to share and reuse the models across them (Klipp *et al.*, 2007). Further, open source, open development software and environments have significantly moved the field forward, which is mostly based on specific programming language including R: Bioconductor (Huber *et al.*, 2015) and python (such as PySB; Systems biology modeling in Python (Lopez *et al.*, 2013)).

On the other hand, data, tools and platforms may not be enough to frame and motivate open-ended collaboration to solve the big problems in science. Bringing humans in the loop, empowered by advanced devices, data and analytics are important to drive new horizons of research in computational systems biology. For example, as a community organization level, the study group at NIH on quantitative systems pharmacology (QSP) proposed the establishment of inter-disciplinary programs for research and training at various levels, ranging from individual teams to multi-investigator, multi-center programs (Ghosh *et al.*, 2013a). Similarly, Kitano *et al.* (2011) have suggested the needs of virtual big science (Kitano *et al.*, 2011), and the community of mathematical modeling and simulation has started identification of the required tools and concepts and possible approaches of integration of existing ones towards whole cell modeling (Goldberg *et al.*, 2018; Karr *et al.*, 2015).

While digital drivers, as identified in this section, do indeed play an important role for the next generation of computational systems biology, social engineering efforts for community engagement will be equally vital to the success of systems biology.

Case Studies in Multi-Dimensional Data Analysis in Systems Biology and Healthcare

Data and computational methodologies in systems biology have become horizontally and vertically extended and no single analytics can handle all of them. When models and tools are independently developed without an explicit strategy on how they can be integrated, they are likely to be inconsistent in their use of data formats as well as operating procedures. Researchers spend a lot of time and frequently face problems of converting data formats, learning tool operations, and even adjusting operating environments. This hinders productivity, counteracts the flexibility in individual workflows and are liable to errors.

How can we ensure the connectivity among multiple tools in one workflow while securing reusability? As discussed in the former section, several integrated platforms have been developed aiming to have a high-level interoperability between tools in a language-agnostic manner. These platforms strive to offer a consistent user experiences and a broader access to a large plethora of tools and resources. The intention of such platform is to host substantial numbers of analytic tools, data resources or knowledge bases such as domain-specific omics database or molecular database.

There are a wide variety of research motivations to participate in various roles to move the Systems Biology field forward (Fig. 3). In this section, we illustrate a case study of multi-dimensional data analysis based on the Garuda platform (Ghosh *et al.*, 2011). We will begin with a brief introduction of the Garuda platform and its features before moving to specific research workflows.

As discussed before, the Garuda platform is a connectivity, discoverability and automation platform striving to seamlessly and intuitively build analytics workflows. One of the key components of the Garuda Platform is the Garuda Protocol which are a series of messages encoded in JSON format that facilitate applications (gadgets) to exchange information. Comprehensive Application

Fig. 3 A wide variety of research motivations for integrated platform-based workflow.

Programming Interfaces (APIs) power connectivity in Garuda. Any application that has been configured to understand these core messages and communicate using them to other tools is said to be “Garudified”. Garudified tools communicate with each other using messages which are coordinated by the Garuda Core. APIs implement the Garuda Protocol in language specific bindings and provide the hooks to communicate with the core. The Garuda core also maintains a gadget graph which depicts the global connectivity of all gadgets in the platform. In addition to connecting existing software tools, one of the attractive feature of the Garuda ecosystem is the ease with which even scripts written in languages like R, python or Perl can be effortlessly wrapped and made into standalone Garudified tools. This facilitates easy sharing and reuse of scripts developed by researchers by making it more visible and available to the community.

Gadgets are distributed using the Garuda Gateway (gateway.garuda-alliance.org). Developers who have garudified their software can list their tools on the gateway with an appropriate license term for the usage of their software. This points to another interesting aspect of the Garuda Platform, the BYOL (bring your own license) model where by while the platform itself is open by design, gadget providers can enforce their own license terms for gadget usage.

There are many interesting use cases of Garuda. For instance, assume that computational analysis was performed on some gene expression data in Garuda. Many times, domain-expert knowledge is required to interpret these analytics results to first gain an understanding of the underlying mechanism as well to point to any gaps. For such cases, deep curated molecular pathway maps (Oda *et al.*, 2005; Oda and Kitano, 2006; Kaizu *et al.*, 2010; Matsuoka *et al.*, 2013) have been made available as a part of Garuda Platform. The results of analytics (which can be a set of gene symbols) can now be mapped onto these maps seamlessly using the Garuda protocol. Practical use cases for Garuda platform are found in a diverse set of applications including clustering, network-based analysis, visualization, machine-learning and mathematical modeling of gene regulatory networks (Hu *et al.*, 2016; Caron *et al.*, 2017; Yachie-Kinoshita *et al.*, 2018). Even for non-specialists, Garuda-compliant software tools offer fast adoptability owing to uniform user-interface guidelines. Garuda platform also provides access to a wide panel of software tools from unrestricted domains without the need for additional learning.

In an example research workflow of oncogenic signaling pathway, researchers may first try to find the mutations associated with a focused cancer subgroup by accessing the sequences of genes encoding the pathway members. They may next predict how the mutations affect the protein structures by searching a three-dimensional protein structure database. Virtual docking simulations can be used to explore possible candidate of kinase inhibitors for the cancer specific signaling. Taking the name of the top-rated inhibitor candidate, they could search for articles of experimental or clinical research reporting the potential effects of the compound or similar compounds on the cell line of interest.

In another scenario, researchers may be eager to know the molecular mechanism of action (MOA), based on the output from the docking simulation. They might want to predict the impact of the kinase inhibitor candidate. In this scenario, they first explore the curated molecular map of the pathway and find the possible influential path from focusing molecule to the molecular end-phenotype such as apoptosis. Next they explore how the candidate inhibitor changes the static path whether a bypass exist. The search for a molecular MOA needs understanding of the dynamics of cell behavior. The researcher may develop or modify existing dynamic simulation model of the pathway to incorporate the mutation-driven changes in the network to predict the cellular dynamics in cancer upon the compounds.

Currently, these entire workflows require a series of separate software tools without information transfer among the tools. A platform successfully integrate these software tools would make such workflows executable with fewer actions, so that researchers can focus on their science rather than on tool operations.

Another key advantage of Garuda is that it can also provide device connectivity and subsequent analytics. Any measurement devices including mass-spectrometers, or any physical devices such as motion sensors and cameras can also be a part of workflow which enables one-stop analysis by connecting the hardware seamlessly with downstream analytics tools (see “Relevant Websites section”). This way experts of various domain other than systems biology, including machine operators, chemist, biologists, data analysts can share the existing and frequently-used workflow in systems biology.

Another interesting use case is when a web-camera takes a picture and using the Garuda protocol automatically sends the data to the next tool where mood detection algorithm is implemented. Such a workflow can be used in clinical settings to monitor patients. Assuming yet another tool downstream of these tools that analyzes the correlation and dynamics between the patient mode and lab results such as blood test and genotype, now the user can have an insight by the integration of phenotypic-level, molecular-level and genetic-level.

Notably, this device connectivity works not only when the device is used as a data source, but also when used as an output. This is realized in the scenario when data analytic tool detects unusual behavior, and can send the alert to doctor's or patient's cell phone in real-time if it is implemented in the platform. Similarly, the connectivity with the device of motion detection, data analytics tools, one can assume the possibility of game-therapy supported by multi-level integrative data such as in diagnosis or monitoring of dementia.

As a whole, the discoverability, navigability and connectivity of multi-dimensional data and analysis are key ingredients that will drive the digital era in biology and medicine (Fig. 4).

Perspectives

Computational systems biology is poised for a paradigm shift standing the cusp of rapidly advancing technologies in experimental systems, data analytics and visualization, machine learning and artificial intelligence (AI) and device technologies.

Fig. 4 Case study of connectivity platform for the integration of phenotypic data and data analytics. Adapted from Yachie, A., Matsuoka, Y., 2016. Systems drug and therapy design. Igaku No Ayumi 259 (8), 853–858 (in Japanese).

As outlined in this article, these developments underscore the importance of combining the digital drivers of research and technologies in multi-disciplinary, community-driven approaches to research in biology and medicine.

Novel experimental techniques to study biological processes at multiple levels in exquisite details have been developed. Similarly, advanced computing and machine learning are allowing researchers to extract hitherto unknown patterns in the data and generate novel hypotheses. In order to connect these diverse tools and methodologies, as highlighted in this article, computational systems biology needs to move towards platforms – large-scale, cloud-enabled frameworks which allow flexible connectivity of these tools to build, execute and re-use research pipelines.

At the same time, the inherent complexity of biological systems, particularly, as manifested in multi-omics scale projects, push the cognitive boundaries of the human mind. As outlined in (Kitano, 2016), several issues emerge in large-scale systems level study of biological processes – information horizon problem, information gap, phenotyping inaccuracy, cognitive bias, and minority report problem. Developments in machine learning, text analytics and robotic automation technologies hold the promise of alleviating some of the problems. It is pertinent to note that unlike other fields where advanced AI have shown unprecedented success, their application in biology and medicine needs to be predicated on explainability and interpretability – the ability to trace the model-based decision-making criteria and interpret the results in the context of the biology.

Intelligent platforms, with humans in the loop and powered by high-precision robotic systems, big data management, analysis and highly explainable and interpretable models will usher in new horizons in computational systems biology towards deeper understanding of biology and its applications in medicine and healthcare.

Coupling Cell Division to Metabolic Pathways Through Transcription

Introduction: The Right Timing of Cell Division

Living organisms have the ability to survive in (un)favourable environmental conditions due to the capacity of their individual cells to grow and divide. The regulation of cell growth and division is realized by the cell cycle, which is set in motion by molecules that regulate and coordinate these events at the right timing.

The cell cycle is defined by four different phases, which are accompanied by strictly ordered and irreversible biochemical reactions. In the G1 phase, the cell grows to a critical cell size that allows it to duplicate its genetic material (DNA) in the S phase, before to continue growing in the G2 phase and, finally, dividing into two daughter cells in the M phase. Because of its crucial role in cell survival, the cell cycle and its component have been conserved across evolution.

In the budding yeast *Saccharomyces cerevisiae*, the maintenance of strictly alternating cycles of DNA duplication and cell division requires a regulator. Dimeric complexes formed by an enzyme, called cyclin-dependent kinase (Cdk1), and a differential pool of phase-specific, regulatory subunits (cyclins) represent the driving force behind cell cycle progression. Cyclin/Cdk1 kinase complexes must be active for entry into S phase and passage through metaphase, and must be inactivated to allow cytokinesis (cell division) in M phase and licensing (activation) in G1 phase of DNA sequences at which new rounds of DNA duplication are initiated. This regulator ensures that each cell cycle phase is completed before the next one initiates, thus guaranteeing alternation between DNA duplication and cell division with a specific temporal delay.

In order to complete these events, periodic waves of cyclin/Cdk1 activities regulate, and are regulated by DNA-binding proteins, called transcription factors (TFs). These proteins stimulate four waves of gene expression (i) at the transition from G1 phase to S phase (G1/S transcription), (ii) in S phase (S phase transcription), (iii) at the transition from G2 phase to M phase (G2/M transcription), and (iv) at the transition from M phase to G1 phase (M/G1 transcription) (Cho *et al.*, 1998; Spellman *et al.*, 1998; Orlando *et al.*, 2008). TFs are activated by cyclin/Cdk activity through biochemical modifications, i.e., phosphorylation, and regulate expression of phase-specific genes throughout the cell cycle. In turn, a transcriptional network drives Cdk activity by stimulating a timely expression of specific cyclin genes. Thus, Cdk activity and the transcriptional network are interlocked to tightly control the timing of cell cycle progression (Bähler, 2005; Wittenberg and Reed, 2005; McNerny, 2011; Haase and Wittenberg, 2014).

The coupling between these cellular layers of regulation has consequences at the system-level. That is, cyclin/Cdk1-mediated waves of gene expression do not just modulate the transcription of cyclin genes at the right timing, but also of a large number of genes involved in the cell's wellbeing. In this context, identification of TFs that may convert a cell cycle response to metabolic switches, and/or that may initiate metabolic reactions whose end products fuel cell cycle reactions, is pivotal to understand how the precise timing of a cell's response is achieved. Ideally, TFs may bridge multiple spatial, temporal and functional scales within various cellular layers of regulation. Thus, they may be hubs (nodes in a network characterized by a high connectivity) at the interface of cellular networks in multi-scale models, which aim to understand how a function emerges from a network of interactions (Castiglione *et al.*, 2014).

By using a Systems Biology strategy, which integrates predictive computer models with biochemical experimentation, we have recently discovered a dynamic coupling of cyclin/Cdk1 complexes to the Forkhead (Fkh) TFs Fkh1 and Fkh2 to guarantee a timely cell cycle progression. Specifically, we have demonstrated that the waves of cyclin/Cdk1 complexes active from S through M phases are synchronized by Fkh2 (and, perhaps, to a lesser extent by Fkh1): S and M phase-specific cyclin/Cdk complexes phosphorylate Fkh2, which in turn promotes expression of S and M phase cyclins (Linke *et al.*, 2017).

The discovery that DNA duplication and cell division are temporally coordinated by Fkh, leads us to ask what is their specific role in the different cell cycle phases. In this study, we aim to understand whether or not Fkh may act as hubs to bridge regulatory processes spanning cell cycle/division, DNA replication, signal transduction and metabolic networks. To this end, we identify targets of Fkh1 and Fkh2 across the budding yeast genome, and indicate whether, and to which extent, a Fkh-mediated transcriptional program leading to the activation of cellular pathways may contribute to the timely cell's cycling. Specifically, we show (i) how definite metabolic pathways may be possibly activated by Fkh, and (ii) their relevance in the synchronization of the cyclin/Cdk1 kinase activities that guarantee alternation of DNA duplication and cell division.

Background: The Interplay Between DNA and Proteins

For the DNA to serve its role as carrier of information in designing proteins in the cell, it is essential to retrieve this information timely and accurately. While protein designs are carried within the DNA sequence, regulation of when and how much of a given protein is produced is achieved by an interplay between the DNA and associated proteins, such as TFs, within the nucleus of eukaryotic cells.

One of the most abundant proteins in the cell are histones, which were first discovered as structural components that DNA wraps around. Chemical modifications of histones were later found to regulate DNA functions, affecting how tightly the DNA-histone complexes are packed and interacting with other proteins to modulate gene expression (Tessarz and Kouzarides, 2014).

The signals that regulate gene expression are integrated at the Transcription Start Site (TSS) of genes by a complex of proteins that includes the RNA polymerase. How different signals can lead to various levels of transcription is not well understood; however, a wide range of cellular components and reactions have been demonstrated to influence this process. In addition to the aforementioned histone modifications, the relative position of a gene in the nucleus has been shown to influence gene expression, introducing the concept of transcriptional factories whereby the expression level of a gene may be influenced by the proximity to an active factory (Papantonis and Cook, 2013).

Another group of proteins influencing transcription through a direct interaction with the DNA sequence is represented by TFs. TFs are defined as proteins that bind to a specific 'motif', i.e., a well-defined DNA sequence, with a typical length of 5–12 base pairs. In budding yeast, TFs are thought to influence transcription, first, by binding relatively close to the TSS, and then by interacting with histones and other TFs on the DNA, thereby influencing the assembly of a productive TSS protein complex. In multicellular eukaryotes, enhancer elements exist that can influence transcription at a long distance from the TSS.

Fundamentals: Methodologies to Investigate DNA–TF Interaction

Understanding how, when and why TFs to DNA has become a major undertaking to understand transcriptional regulation. The first genome-wide method realized to experimentally map TF binding across the genome in living cells was Chromatin Immunoprecipitation (ChIP) with microarray detection of bound DNA (ChIP-chip) (Solomon *et al.*, 1988). This technique relies on: (i) Using formaldehyde to chemically link proteins and DNA together, (ii) sonicating the DNA to fragment it, (iii) purifying a selected protein by antibody, and (iv) detecting the DNA fragments that are bound to the purified protein. Studies that have mapped the DNA binding sites of many TFs provided the first integrated view of the proteins and regulatory mechanisms that control eukaryotic gene expression (Harbison *et al.*, 2004).

With the emergence of next generation sequencing, further development of the ChIP methodology led to ChIP-seq (Robertson *et al.*, 2007), which could achieve higher resolution as compared to ChIP-chip because of not being limited by the amount of probes on the chip. Multiplexing with barcoded adaptors and increased availability of commercial sequencing services have lowered the costs of ChIP-seq experiments, to a point where it has now replaced ChIP-chip as the dominant method of genome-wide determination of TF binding to the DNA (Park, 2009). Importantly, ChIP-seq was used as the method of choice for the ENCODE consortia to map a large number of human TFs with a consistent set of experimental and data processing protocols (Landt *et al.*, 2012).

The latest development of the ChIP methodology is called ChIP-exo, which further ameliorate ChIP-seq by using an exonuclease to degrade one strand of the isolated DNA (Rhee and Pugh, 2011). The exonuclease cleaves one DNA strand until the TF – DNA crosslink, and adaptors are then ligated to the cleaved ends, leading to a high resolution information of the TF – DNA contact surface. The general ChIP protocol and differences among the three ChIP methods are illustrated in Fig. 1, whereas the main advantages between ChIP-seq and ChIP-exo are listed in Table 1. An impressive demonstration of the increased resolution of ChIP-exo was the mapping of components of the pre-initiation complex in budding yeast. In this study, the area of DNA that was protected by the exonuclease was a good match for how a specific protein was predicted to cross-link to the DNA from a model of DNA and protein structures (Rhee and Pugh, 2012).

Fig. 1 Summary of the ChIP experimental protocol and overview of the main differences between three ChIP methods: ChIP-chip, ChIP-seq and ChIP-exo (see text for details).

Table 1 Advantages of ChIP-seq and ChIP-exo when compared to each other

<i>ChIP-seq</i>	<i>ChIP-exo</i>
– Easier and quicker experimental protocol – Fewer costly reagents – More developed tools for data analysis – Immunoprecipitation control allows for the analysis of unspecific antibody binding	– Higher resolution mapping of TF–DNA binding – Footprinting several TFs can provide structural insights of protein complexes – Less background binding to the DNA due to exonuclease treatment

The choice of which ChIP methodology to use when investigating a given TF is not obvious, and several factors should be considered. Although ChIP-exo is the most recent development and seems to be the most attractive choice if the resources are available, new challenges are introduced when using this ChIP methodology as compared to ChIP-seq. Notably, a treatment with the exonuclease makes it impossible to have an immunoprecipitation (IP) control, as typically used in ChIP-seq experiments. Recently, an interesting solution to this problem, called protein attached chromatin capture (PATCh-Cap) (Terooatea *et al.*, 2016), was proposed. PATCh-Cap seems to increase the confidence in peak identification; however, it remains untested at a large scale to exclude any introduction of bias. The lack of an IP control means that the most common ChIP peak quantification metric, i.e., ChIP peak signal/IP control signal, is no longer possible and other metrics have to be used. While the lack of an IP control complicates the measurement of a ChIP peak signal, ChIP-exo seems to have a reduced level of background binding as compared to ChIP-seq (Rhee and Pugh, 2011), resulting in a potentially more accurate quantitative measurement of TF binding to the DNA. In addition, an increased resolution given by the exact position of the TF binding event can potentially be used in a system-level analysis to describe gene regulation in detail.

The network of cellular signals that regulate expression of a gene or of a group of genes is often referred to as Transcriptional Regulatory Network (TRN). While a variety of signals affects gene transcript levels, much of the current studies focus on TFs. Importantly, in recent years, the power of system-level analyses that integrate TF binding information with transcriptome analysis has been demonstrated, for example to understand the bacterial TRN of gene expression (Arrieta-Ortiz *et al.*, 2015; Fang *et al.*, 2017). Although many details are known about eukaryotic gene regulation, a TRN with demonstrated predictive power is lacking. This is partially due to the fact that the eukaryotes genome comprehends more genes and TFs, and that additional complexity exists that is introduced by histone occupancy and modifications, TF subcellular localization and a variety of post-translational modifications. These additional levels of regulation mean that more information needs to be taken into account in a system-level analysis to understand how eukaryotic TRNs regulate gene expression.

ChIP data provide a list of targets of TFs that may be subsequently analyzed for their specific function within cellular networks. Given the wealth of data that is available about genes and the proteins they encode, ChIP data can predict novel functions of TFs. When retrieving these data, a number of challenges are faced: (i) False-positives binding events have to be excluded, and (ii) a comprehensive picture of the TF functions from the wealth of data generated shall be drawn. In this study, we present and discuss our approach to dealing with these challenges when investigating the Fkh-mediated transcriptional program. A picture of Fkh's functions within the multi-scale network of the budding yeast cell demonstrates the power of the ChIP methodology to generate hypotheses and suggest definite experiments that may shed light on novel regulatory events underlying timely cellular responses upon stimulation.

Application: Chip Data Formats

Choosing the ChIP methodology to study TF binding events should take into account the differences in data processing between these, in addition to those in the experimental protocols. ChIP-seq is currently well established, and a major resource is represented by the detailed experimental protocols and data processing pipelines that have been established for the ENCODE consortium experiments (Landt *et al.*, 2012). In the following, we will describe briefly the main established protocols currently available for the identification of a ChIP-seq signal, and the alternative approaches that we have developed for analyzing ChIP-exo data.

Established Peak Detection Protocols: GEM and MACE

One of the data analysis tools selected for the ENCODE ChIP-seq experiments is called GEM (Genome wide Event finding and Motif discovery) (Guo *et al.*, 2012). GEM (i) determines the shape of peaks corresponding to TF binding events on the DNA (peak detection), and motifs enriched in the most common peaks in a given sample, and (ii) iterates on both peak shape and motif to enrich the dataset for peaks that generate a weaker signal with a similar peak shape and motifs. This strategy can also be used to analyze ChIP-exo data; however, the main limitation is the need for a large number of peaks to reliably iterate the procedure.

Another peak detection tool is called MACE (Model based Analysis of ChIP-Exo) (Wang *et al.*, 2014). MACE separates the reads of different DNA strands and searches for a definite distance (called 'border pair') between the start of reads that is enriched across the sample. The enriched border pair distance should correspond to the size of the TF – DNA interaction surface. A set of clear (strong) peaks defined as 'elite border pairs' is required for the analysis, in order to have a reliable starting point to define the remaining weaker peaks. Thus, the limitations of MACE are similar to GEM, with a requirement for a relatively large amount of strong peaks.

Alternative Approaches: *maxPeak* and *loessPeak*

While studies of human TFs binding to DNA typically provide a sufficient number of peaks to be analyzed by iteration-based peak detection methods, our experience with budding yeast indicates that not all TFs will have enough targets to achieve a reliable iteration procedure when using GEM or MACE. This led us to develop alternative tools to define peaks that are not dependent on iteration, thus that can process data containing fewer peaks. To define what a peak is, relative to an uneven background signal, is not a trivial task when only relatively few peaks are detected.

According to the principle of ChIP-exo, the positions inside the TF – DNA binding surface should be highly enriched for overlapping reads from each DNA strand, while unspecific reads from experimental background or technical noise may be on only one DNA strand. One approach that we have developed is to reduce the background signal by using the strand-specific information and counting up reads only where there were reads overlapping on each DNA strand; we will denote this approach by OL, for overlapping DNA strand, as opposed to AD, for additive DNA strand approach. The term ‘overlap’ is here to be interpreted as having, at a minimum, one read on each DNA strand covering the same single nucleotide position. Hence, these two reads overlap on that nucleotide, albeit on different DNA strands.

To further reduce the background noise, we determine a read length to be used where a TF binding site is covered by reads on each strand, but not extending out on each side. Reads coming from our experimental setup have a length of 75 base pairs, and choosing a read length of 10 would correspond to taking the left-most 10 base pairs into account. The exact read length to be used is tested by quantifying the highest point of overlapping reads per gene for read lengths from 1 to 75 base pairs, and by selecting the read length where the increase in highest peak counts is most increased over the previous three read lengths. For the Fkh TFs investigated in this study, this read length was determined to be equal to seven. Given the read length, each read is shortened to correspond to the read length (starting to count at the left-most base pair). Given the read length, either through the optimisation procedure indicated above or by choosing it manually, and the approach for dealing with the strands, OL or AD, we will hereafter denote the combination of these two as e.g., OL7 or AD10, for read lengths of 7 or 10 base pairs, respectively.

When investigating TF binding events, a choice has to be made with respect to the part of the genome to be explored. Two options may be considered: (i) Use of the known TSS for the subset of genes for which this information is available, and search 1000 base pairs upstream of TSS, or (ii) use the known locations of the ORF (Open Reading Frame) for each gene, and search 1000 base pairs upstream of the start codon. The choice of a region of 1000 base pairs is somewhat arbitrary, but is limited by the fact that a too large region might end up in the ORF of an upstream gene. The advantage of the former approach is that transcription starts from the TSS so it defines a more accurate region as the promoter of a gene, whereas the advantage of the latter is that information can be retrieved from a higher number of genes even if the TSS location is unknown. In practice, the difference of using the two approaches is minimal for the majority of genes that have a defined TSS, which have a distance from the TSS to the start codon of about 20–80 base pairs. In a parallel study, we have considered TSS from the study of Iyer and colleagues (Park *et al.*, 2014) as well as 166 manually added approximate TSSs based on RNAseq data, for a total of 5373 TSSs (unpublished). Here, we instead search upstream of the start codon of the ORF for each gene.

At this point, the ChIP-exo dataset consists of short reads, overlapping on one (AD) or both (OL) DNA strands, which we can count at each base pair. Consequently, a series of peaks of different heights may be retrieved along the genome. In this work, we present two novel approaches to determine TF binding locations on the DNA, which we refer to as ‘maxPeak’ and ‘loessPeak’.

In the maxPeak approach, we locate the base pair with the highest count of reads for each gene’s promoter region. This means that only one TF binding location for any given gene may be found. As previously mentioned, a challenge with ChIP-exo as compared to ChIP-seq is the lack of an antibody immunoprecipitation (IP) control that can be used to measure quantitatively a specific TF – DNA enrichment relative to an unspecific antibody – DNA enrichment. In order to have a relative measurement of the peak strength (signal/noise) and to remove the background signal, we detect peaks by using peak quantiles. Quantiles are calculated from the maximum signal per gene promoter of all promoters that have any signal. Our experience from ChIP-exo analysis of other budding yeast TFs is that the 65% quantile (the 65th percentile) is a threshold that results in a good representation of peaks as well as removal of the majority of the background and noisy signal (unpublished observations). In contrast, the signal/noise for GEM is calculated by dividing the IP signal of the peak by the ‘expected binding strength’ that calculates the background signal in the local context around the detected peak. In MACE, peak significance is reported as a p-value. A subtlety to take into account when considering the 65th percentile threshold is that a similar background noise may be assumed across experiments based on different conditions (e.g., different growth) for the same TF. In these cases, it may be useful to average the threshold for the conditions and use the new value as the normalizing factor. We will return to this specific point in the section of the ChIP data analysis.

After applying the maxPeak approach, and before applying the loessPeak approach, TF binding sites may be ordered by the height of their signal. In the maxPeak approach, this corresponds to the number of reads at the peak binding position (i.e., zero or one location per gene). For the loessPeak approach, this corresponds to potentially many peaks per gene. For either approach, TF binding locations may first be sorted in ascending order and then reduced by applying the threshold of the 65th percentile, which is chosen as the quantile threshold to consider a binding position non-random. For the maxPeak approach, the signal of each identified peak is then normalized (divided) by this quantile, yielding a Signal-to-Noise Ratio (SNR) below 1 if the location has a lower signal than the threshold and a SNR > 1 if its signal is above the threshold. For the loessPeak approach, any signal in the promoter that is below the 65th percentile is set to that value.

In the loessPeak approach, after leveling any signal below the 65th percentile, the signal at the promoter is smoothed with a loess function using a span of 0.05. This is only a mild amount of smoothing where the main goal is to get an accurate position of the

highest point of the peak while also having a small differential effect on strong and weak peaks. The smoothing causes weak peaks that are, for example, very narrow to be relatively reduced as compared to wider and stronger peaks. Subsequently, peaks are identified by searching for a pattern signal change in the smoothed signal containing minimum 7 consecutive increasing signal values and then minimum 7 consecutive decreasing signal values. For a gene, all identified peaks are listed by order of signal strength and, if a lower peak signal is within 100 base pairs of a stronger peak, the weaker one is discarded. All peaks are then normalized by the 65th percentile. Generally, peaks with a remaining, smoothed and normalized, $\text{SNR} < 1$ are discarded.

Biological duplicates are explicitly averaged in the maxPeak and loessPeak approaches when the number of reads for each nucleotide is quantified. GEM and MACE internally deal with the biological duplicates.

The workflow of our experimental protocol, starting from ChIP-exo sequencing reads, is summarized in [Fig. 2](#), whereas a visualization of the maxPeak and loessPeak approaches is shown in [Fig. 3](#).

Case Study: ChIP-exo Data Analysis of Fkh1 and Fkh2 TFs

The Forkhead (Fkh) TFs Fkh1 and Fkh2 modulate a timely cell's cycling in budding yeast, by coordinating DNA duplication with cell division. Fkh2 is expressed from the G1 phase until the M phase, with Fkh1 overlapping during S and G2 phases ([Lee et al., 2002](#)).

In the G1 phase of the cell cycle, Fkh guarantee the right spatial organization of chromatin within the nucleus of yeast cells. Specific DNA binding sites, called origins of replication or replication origins, timely cluster prior DNA duplication and are subsequently recognized by enzymes (DNA polymerases) that initiate this process. Fkh1 and Fkh2 were shown to be involved in this mechanism by binding to, and regulating the transcription timing of a number of replication origins ([Knott et al., 2012](#); [Ostrow et al., 2014](#)) by acting as rate-limiting activators ([Peace et al., 2016](#)). We have also demonstrated that Fkh proteins are responsible for the clustering of replication origins in the S phase, thereby of the timing of DNA duplication, through a structural motif that allows dimerization to bring distal DNA binding sites into close proximity ([Ostrow et al., 2017](#)).

Fkh-dependent activity also drives transcriptional regulation of genes at the G2/M transition, in particular of the *CLB2* cyclin gene promoting cell division ([Koranda et al., 2000](#); [Kumar et al., 2000](#)). Although Fkh1 and Fkh2 have overlapping functions, only Fkh2 can form a complex, together with the scaffold protein Mcm1 and the co-activator Ndd1, that binds to and modulate the activity of both *CLB2* and *CLB3* promoters ([Koranda et al., 2000](#); [Kumar et al., 2000](#); [Pic et al., 2000](#); [Reynolds et al., 2003](#); [Linke et al., 2017](#)). Conversely, Fkh1 binds less efficiently to the *CLB2* promoter and represses *CLB2* transcription ([Hollenhorst et al., 2000, 2001](#); [Sheriff et al., 2007](#)).

Fkh expression and function throughout cell cycle progression suggests that these TFs may have the potential to establish regulatory interactions with cellular networks beside the cell cycle. Therefore, in this study, we have explored the capability of Fkh1 and Fkh2 to bind promoters of genes across the budding yeast genome through ChIP-exo. ChIP data have been gathered under two different experimental conditions (cells grown exponentially, or logarithmic phase, and in stationary phase) to compare the data analysis tools described above, and their challenges and advantages will be highlighted in the following. Fkh1 and Fkh2 have an intermediate amount of peaks as compared to other budding yeast TFs (unpublished observations), thus may serve as good case studies to test the workflow and challenges in working with ChIP-exo in this organism. The workflow shown in [Fig. 2](#) has been implemented in this study for the Fkh1 and Fkh2 data analysis.

Challenges With GEM and MACE

GEM did reliably iterate on Fkh1 data (two different experimental conditions, two biological replicates of each condition), but not on Fkh2 data. Considering that Fkh1 and Fkh2 are proposed to have similar binding motifs ([de Boer and Hughes, 2012](#)), we ran Fkh1 and Fkh2 data together in the GEM analysis, treating them as different conditions of the same TF. As a result, a reliable iteration was possible for both data. Similarly, MACE also presented challenges when analyzing Fkh2 data; the detected amount of elite border pairs was only 25, and the MACE python script by default fails with less than 30 elite border pairs. Therefore, the script was modified to reduce the existing threshold, thus allowing us to analyze the data for Fkh2 as well.

Determination of the Read Length

As described above, the OL and AD approaches applied to the maxPeak and loessPeak methods of peak detection do not require iteration or minimal numbers of peaks of a certain quality. Data analysis was performed four times: the optimal read length was determined to be 7 base pairs for both Fkh1 and Fkh2; however, in order to test the sensitivity to the read length setting, we have also performed the analysis for a manually determined read length of 10 base pairs. For both read lengths we performed the analysis by using the overlapping DNA strand approach (OL) and the additive DNA strand approach (AD). In [Fig. 4](#) the raw reads and peak detection results are visualized for the four data analysis methods (maxPeak, loessPeak, GEM and MACE,) for the genes *PES4* (coding for a poly(A) binding protein) and *CLB2* (coding for a mitotic cyclin that promotes the transition from the G2 to M phase), which have the highest SNR for Fkh1 and Fkh2, respectively.

In [Fig. 5](#) the signal of the peaks against the percentiles of raw data for both Fkh1 and Fkh2 is plotted. As previously mentioned, based on prior experience, the 65th percentile represents a good threshold, and it also seems to be a good choice to analyze Fkh1 and Fkh2 data. In fact, this value sits in a relatively flat area of the curves where the difference between both TFs is not too large.

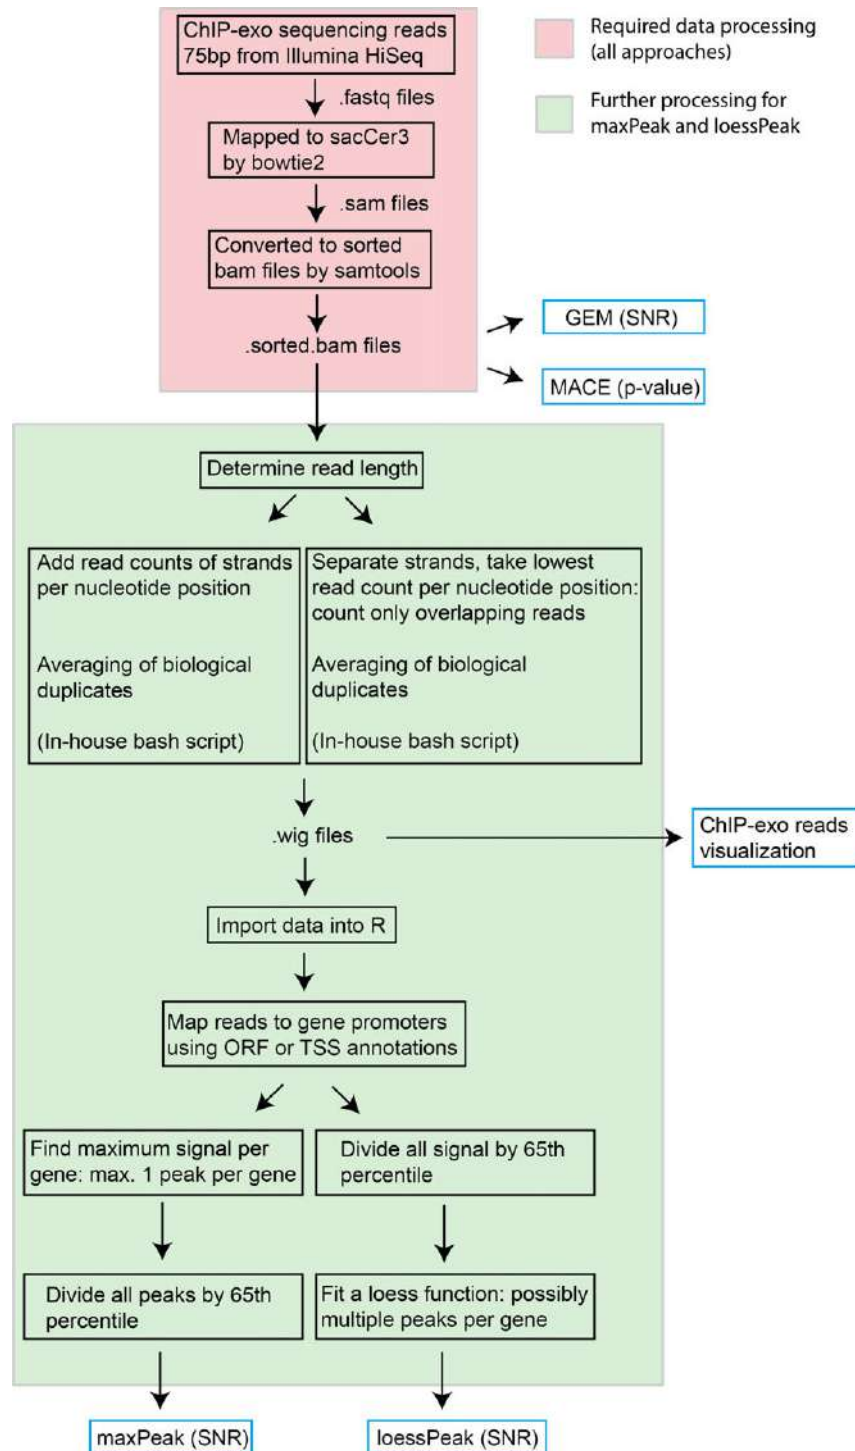

Fig. 2 Overview of the ChIP-exo data analysis workflow. To map reads to the budding yeast genome, raw reads were mapped to the SacCer3 genome (S288C_reference_sequence_R64-2-1_20150113.fsa, downloaded from the Saccharomyces Genome Database (SGD) website (see “Relevant Websites Section”) with Bowtie 2. (Langmead and Salzberg, 2012). SAM files were converted to BAM files, sorted and indexed using SAMtools (Li *et al.*, 2009). Output indicated as blue rectangles is shown in Fig. 5.

Data Integration and Annotation

After ChIP data processing was completed, we have integrated and annotated the data to retrieve biological information. We have recently developed GEMMER (see “Relevant Websites section”), a web-based visualization tool of multi-scale interaction networks that integrates information from various databases for budding yeast (Mondeel *et al.*, 2018). The ChIP data were merged with the

Fig. 3 Illustration of the maxPeak and loessPeak approaches. The workflow depicted applies to each gene in the genome. Reads are counted across all base pairs within the promoter region of a gene. The maxPeak approach (left) identifies a single nucleotide with the highest read count in each promoter region. The genome-wide 65th percentile is calculated, and used to normalize the read count of each peak, generating a Signal-to-Noise Ratio (SNR). In contrast, the loessPeak approach (right) starts by calculating and normalizing the peak signals by the genome-wide 65th percentile of the highest point of all genes that are > 0 , and then applies a loess smoothing function; finally, any remaining peaks with a $\text{SNR} \geq 1$ are identified.

gene annotations contained in GEMMER. This process has extended the experimental data available for each protein-coding gene in SGD, with information regarding functional annotation, localization, abundance, and both timing and cell cycle phase of peak occurrence of RNA transcript levels. Thus, this step allows for a number of novel analyses of the ChIP-exo data. Of note, the vast majority of genes reported by the data analysis are protein-coding genes; however, some exceptions exist.

Comparing Data Formats and Peak Detection Methods' Performance

We have explored the number of genes and peaks detected for the four different peak detection methods introduced above, and we found significant differences in the number and locations of peaks detected (see Fig. 4). Moreover, as previously mentioned, the quantile determination may be performed independently for each experimental condition, or determined as average for multiple conditions for each TF. We will therefore briefly explore the difference for the Fkh1 and Fkh2 datasets with respect to these different determinations.

Table 2 reports the number of TF binding locations above threshold in unique genes and the (equal or larger) number of distinct peaks for GEM ($\text{SNR} \geq 1$), MACE ($p\text{-value} \leq 0.01$), maxPeak (OL7 and AD10 with $\text{SNR} \geq 1$) and loessPeak (OL7 and AD10 with $\text{SNR} \geq 1$) when determining the average quantile for both experimental conditions (growth of cells in logarithmic phase or in stationary phase) for each TF. Similarly, Table 3 reports the number of peaks and genes retrieved when the quantiles are determined independently for each experimental condition. Of note, only the maxPeak and loessPeak approaches are affected by the choice of the quantiles (see workflow in Fig. 2). In Table 2 a significant increase in genes/peaks may be observed in stationary phase for both Fkh1 and Fkh2 as compared to the logarithmic phase, when using maxPeak and loessPeak. This evidence suggests that the assumption of an equal background noise across these conditions may be not realistic. In Table 3 a reduced ratio of genes/

Fig. 4 Analysis of ChIP-exo reads (top part of panels) by different peak detection methods for two genes. (A) *CLB2*, selected for having the highest peak for Fkh2. (B) *PES4*, selected for having the highest peak for Fkh1. The maxPeak (OL7) approach returns a single peak for in the promoter region of both genes. GEM and loessPeak may return multiple peaks, whereas MACE returns a region of several consecutive nucleotides as the peak.

peaks across experimental conditions may be observed, although a large increase in the signal above threshold still occurs in stationary phase experiments. For example, the ratio of target genes identified by maxPeak OL7 between the two conditions for Fkh1 changes from $747/1422=0.525$, to $816/1363=0.599$. We have proceeded to analyze ChIP data based on quantiles determined independently for each experimental condition.

Investigating the Discrepancy Between OL7 and AD10

So far we have been considering the AD10 dataset as a simultaneous illustration of the additive approach to counting reads on both DNA strands, and of the change of the read length. Tables 2 and 3 clearly point out that large differences exist in the analysis between the OL7 and AD10 datasets, even within one approach, e.g., maxPeak. In Fig. 6(A) the fold-change in the SNR among three sets of genes is shown when using the maxPeak OL7 and AD10 datasets for Fkh1 in logarithmic phase: (i) The 100 genes with the highest signal in OL7, (ii) all genes in OL7 with a $SNR \geq 1$, and (iii) all genes in OL7 with a $SNR > 0$. Large fold changes are observed in all three groups. This difference is more apparent in Fig. 6(B), where the difference in rank for genes in each of the three groups is plotted. The term 'rank' here indicates the index of a given gene when the dataset is sorted on the SNR in descending

Fig. 5 Peak percentiles across all genes with signal >0 for two data formats explored. (A) Summing up all read counts per nucleotide position with 10 base pairs long reads (AD10). (B) Counting only overlapping reads per nucleotide position with 7 base pairs long reads (OL7). It can be observed that the signal is lower in the OL7 approach, due to the more stringent approach of only taking overlapping reads on both DNA strands.

Table 2 Unique target genes and total peak counts for TF normalized data (averaged across experimental conditions) analyzed by four peak detection methods. A low threshold was used for considering target genes significant (see text), and for maxPeak and loessPeak both overlapping (OL) and additive (AD) DNA strand approaches were applied using read lengths of 7 and 10 base pairs, respectively. Of note, for the maxPeak approach the number of genes and peaks is always equal

	<i>maxPeak OL7</i>		<i>maxPeak AD10</i>		<i>loessPeak OL7</i>		<i>loessPeak AD10</i>		<i>GEM</i>		<i>MACE</i>	
	<i>Genes</i>	<i>Peaks</i>	<i>Genes</i>	<i>Peaks</i>	<i>Genes</i>	<i>Peaks</i>	<i>Genes</i>	<i>Peaks</i>	<i>Genes</i>	<i>Peaks</i>	<i>Genes</i>	<i>Peaks</i>
Fkh1 mid-log	747	747	1880	1880	726	779	1786	2116	215	221	439	451
Fkh1 stationary	1422	1422	3029	3029	1372	1564	2923	3937	248	259	814	841
Fkh2 mid-log	686	686	755	755	628	655	713	783	132	139	691	699
Fkh2 stationary	2944	2944	4170	4170	2800	3497	4055	5940	170	184	1142	1196

order. A negative index indicates a lower rank in the AD10 dataset, whereas a positive rank indicates a higher rank in the OL7 dataset. Strikingly, there are large shifts in rank that correspond with the fold changes; even among the top 100 OL7 targets there are genes that shift down hundreds of places in AD10.

What is the reason for the observed difference? In [Fig. 6\(C\)](#) and [\(D\)](#) the same fold change and rank displacement analysis is reported when comparing OL7 and OL10. Here, the differences are almost insignificant, especially among the genes with a higher signal. It appears that changing the read length from 7 to 10 base pairs has only a little consequence to the data analysis. To drive the point home, in [Fig. 6\(E\)](#) and [\(F\)](#) the same analysis is performed among OL7 and AD7 datasets. The similarity with [Fig. 6\(A\)](#) is remarkable. Therefore, we conclude that the maxPeak and loessPeak (the latter not shown) approaches are relatively insensitive to the read length setting, but very sensitive to the choice of how to deal with reads on different DNA strands. Given that the OL approach reduces the background noise – as it is intuitively apparent and reflected in the number of genes/peaks reported in [Tables 2](#) and [3](#) –, we hereafter proceed considering only the OL approach with a read length of 7.

Increasing the Stringency for TF Binding Significance

Analyzing in more detail [Table 3](#), it can be observed that GEM is the most stringent among the peak detection methods by far in terms of the number of genes and peak locations it returns as being significant. Following the results shown in [Fig. 6](#), we have realized that especially the maxPeak and loessPeak approaches may overestimate the number of significant TF binding events when using a threshold of $\text{SNR} \geq 1$. Therefore, we have repeated the data analysis for more stringent thresholds with the aim of uncovering the more reliable Fkh target genes (see [Table 4](#)).

Table 3 Unique target genes and total peak counts for condition-normalized data analyzed by four peak detection methods. A low threshold was used for considering target genes significant (see text), and for maxPeak and loessPeak both OL and AD DNA strand approaches were applied using read lengths of 7 and 10 base pairs, respectively. Of note, for the maxPeak approach the number of genes and peaks is always equal

Fig. 6 Comparison of the rank displacement and SNR log10 fold-change between the maxPeak OL7 and AD10 datasets for Fkh1 in logarithmic phase.

Table 4 Unique target genes and total peak counts for condition-normalized data analyzed by four peak detection methods. A higher threshold was used for considering target genes significant (see text), and for maxPeak and loessPeak only the OL DNA strand approach was applied using a read lengths of 7 base pairs. Numbers highlighted in red color indicate the condition for a particular dataset that approximately reaches the number of genes retrieved by GEM for definite stringency settings

	<i>maxPeak OL7</i>		<i>loessPeak OL7</i>		<i>GEM</i>		<i>MACE</i>	
	<i>Genes</i>	<i>Peaks</i>	<i>Genes</i>	<i>Peaks</i>	<i>Genes</i>	<i>Peaks</i>	<i>Genes</i>	<i>Peaks</i>
Fkh1 mid-log	348	348	287	301	215	221	219	223
Fkh1 stationary	530	530	467	496	248	259	403	408
Fkh2 mid-log	452	452	360	370	132	139	191	193
Fkh2 stationary	167	167	169	169	170	184	281	282

To this aim, we used a heuristic approach: We leave GEM stringency as is, and we increase the thresholds for maxPeak, loessPeak and MACE independently, until one of the four experimental conditions reaches the same or similar number of target genes as GEM returns. Importantly, these are not necessarily the same genes, but just the same number of genes. We therefore retained GEM as the ‘upper bound’ on the stringency and tried to match it with the other peak detection methods. In the end, we decided on thresholds of $\text{SNR} > 1.5$ for maxPeak, $\text{SNR} > 1.123$ for loessPeak and $p < 0.0052$ for MACE. The number of genes retrieved using these thresholds is reported in Table 4.

System-Level Insight From the ‘Common Core’ of Retrieved Target Genes

After having reduced the number of ‘significant’ Fkh target genes as shown in Table 4, we may ponder how divergent are the genes identified by each of the four peak detection methods with regard to the target genes retrieved by all methods. In Fig. 7 Venn diagrams are shown that indicate the overlap of the number of target genes among the four peak detection methods, across the four different experiments.

Strikingly, only a small overlap is observed among the four peak detection methods. Even among the published tools, GEM and MACE, the number of target genes that are not retrieved by the other methods is remarkable. Apparently, even among the targets that show a relatively high signal there is a large variation among the four methods. A number of reasons may be considered for explaining the discrepancy: (i) GEM and MACE did have issues when analyzing the Fkh2 ChIP dataset; (ii) the four peak detection methods might recognize different signal signatures; (iii) the thresholds used might be not sufficiently stringent, i.e., when looking only at the top scoring targets in each method, these might retrieve the same genes. The latter point does not seem to hold, based on our attempts to increase the binding stringency further: We did not observe an increase in the ratio of overlapping genes to total genes reported as significant.

In Table 5 the genes retrieved as significant Fkh targets by the four peak detection methods are listed by their standard name (if available). We refer to these genes as the ‘common core’. Importantly, the known main target (i.e., positive control) of Fkh2, the *CLB2* gene, is among the genes within the common core, and it is retrieved by all peak detection methods in both logarithmic and stationary experimental conditions. Interestingly, the common core of Fkh1 targets includes a large subset of metabolic enzymes (10 out of 77), whereas only two metabolic enzymes (*PMA1* and *IDI1*) out of 19 are retrieved by all four methods for Fkh2. Four previous ChIP studies have reported target genes of both Fkh1 and Fkh2 (MacIsaac *et al.*, 2006; Hu *et al.*, 2007; Venters *et al.*, 2011; Ostrow *et al.*, 2014); we have taken this information into account, and we have indicated in Table 5, in red color, those target genes that have not been reported by these studies.

In a previous study 1082 genes have been identified as being cell cycle-regulated, and the time of their expression peak as well as the cell cycle phase where it occurs was reported for each such gene (Kudlicki *et al.*, 2007; Rowicka *et al.*, 2007). The common core of target genes can be verified for the presence of cell cycle regulated genes as well as for their functional annotation through the merge with GEMMER. In GEMMER, the GO (Gene Ontology) term annotations – which provide the logical structure of the biological functions (‘terms’) and their relationships to one another – are retrieved for each gene in SGD, and traced back through the hierarchical tree of GO terms to one of the following high-level GO terms: *Cellular metabolic process* (GO:0044237), *Cell cycle* (GO:0007049), *Cell division* (GO:0051301), *Signal transduction* (GO:0007165), and *DNA replication* (GO:0006260). These terms fall under the GO term *Cellular process*, with *DNA replication* falling under *Cellular metabolic process*. In GEMMER each such GO term annotation is assigned to one of the high-level terms listed above. For each gene, GEMMER adds up the number of annotations that fall under each high-level GO term. The GO term with the highest count is then assigned as the gene’s primary function.

In Fig. 8 all cell cycle-regulated genes in the common core (44 out of the 88 unique genes listed in Table 5) are displayed for all four experimental conditions, and grouped across the cell cycle phase where their expression peak occurs. It can be observed that the majority of the cell cycle-regulated genes that are Fkh targets fall within the GO terms *Metabolism*, suggesting their function especially in the S phase for DNA duplication, and primarily activated by Fkh1. A large number of the common core genes are Fkh1 targets, which exhibit their expression peak throughout all cell cycle phases, in particular in G1(P) (pre-replicative G1), G1/S, S and M phases. Conversely, Fkh2 targets are mostly concentrated in G2 and G2/M phases, such as *CLB2*. Several targets of Fkh1

Table 5 Target genes in the ‘common core’, i.e., target genes retrieved by each of the four peak detection methods discussed in this work. Genes encoding a metabolic enzyme are indicated in bold. Genes that have not previously been observed as Fkh targets in previous ChIP studies are indicated in red color

Experiment	Target genes retrieved by maxPeak, loessPeak, GEM and MACE
Fkh1 logarithmic	ALG5, BRN1, DIN7, EGO2, ERS1 , ESP1, EXG1 , FLR1, FRK1 , HOS3, IDI1 , KIP2, NEW1, OSH7, PES4, RNR1 , RPS1B, SUN4, TEL2, TEM1, VIK1, YLR299C-A , YPL251W
Fkh1 stationary	ABP140, ADH4 , AIM46, ALG5, ARK1, BRN1, BUD3, BUD8, CIK1, CIT2 , CSI1, CSN9, DCC1, DIT1 , DIT2 , DSE2 , ECM10, EDC3, FHL1, FIN1, FIR1, FLR1, FRK1, GAS3, HOS3, HXT5 , IDI1 , KIP2, MKK2, MNT2, MUM3, NBL1, NEW1, NPP2, NUP2, NVJ3, OSH7, PDS5, PES4, PMA1 , RNR1 , RPL39, RPL8A, RPN10, RPN11, RPS1B, RPS22A, SAS3, SFG1 , SGO1, SPC24, TDA7, TEM1, TIM18, TMN2, TRS85, VIK1, VTI1, WTM1, YCS4, YGL007C-A, YGR111W, YLR334C, YMC2, YNL174W, YOR314W-A , YPI1, YPL251W, YPT31
Fkh2 logarithmic	CIS3, CLB2, ENV9, PMA1 , SRL1, YGL007C-A, YOR248W
Fkh2 stationary	ASE1, BUD4, CLB2, CLN1, HOS3, IDI1 , JSN1, KIP2, MTC6, OSH7, SFG1 , SPO12, YOR314W-A

and Fkh2 have their primary function in the cell cycle, e.g., *KIP2*, *CIK1*, *ESP1*, *VIK1* (Fkh1 targets) and *CLN1*, *CLB2* (Fkh2 targets). Noteworthy, a non-cell cycle target for Fkh1 is *RNR1*, the large subunit of the ribonucleoside-diphosphate reductase (RNR) that catalyzes the rate-limiting step in dNTP synthesis.

Fig. 8 Stack plot representing cell cycle phase of peak expression for the common core of Fkh target genes. Genes are retrieved by all four peak detection methods, for four experimental conditions, and are grouped according to the cell cycle phase of peak expression, as reported (Rowicka *et al.*, 2007). Each gene is indicated as a rectangle, and the colors of each rectangle indicate a specific gene function. The colors (white, red, yellow and green) of the smaller rectangles on the side of a gene indicate the experimental condition in which a gene was found as Fkh1 target (upper) and/or Fkh2 target (lower), respectively. Genes encoding a metabolic enzyme are indicated in bold. Vertical ordering is based on alphabet of the standard gene name.

Table 6 Enrichment of global function of Fkh target genes compared to the set of all protein-coding genes (genome-wide %). The percentages in the last four columns (Fkh1 logarithmic, Fkh1 stationary, Fkh2 logarithmic and Fkh2 stationary) are calculated with respect to the “Genome-wide %” column. The genes considered for the last four columns are considered to be significant at least by *one* of the four peak detection methods for the chosen thresholds (see text)

Functional category	Genome-wide %	Fkh1 logarithmic %	Fkh1 stationary %	Fkh2 logarithmic %	Fkh2 stationary %
Metabolism	75.65	−6.90	−6.21	−6.74	−6.93
Cell cycle	11.99	1.33	0.85	0.71	2.69

Cell division	4.54	0.66	−0.38	1.22	1.22
DNA replication	0.96	−0.4	0.26	−0.34	−0.13

Exploration of Unique Sets of Fkh Targets Unravels Regulatory Links With Metabolism

The relatively small number of common core target genes retrieved by all four peak detection methods provides an insufficiently large dataset to systematically compare enrichment in function and timing. Therefore, we have considered the larger set of genes that, for each independent experiment and experimental condition, is retrieved as a Fkh target using the stringent thresholds by at least *one* method. In other words, this set of genes is the set of unique genes indicated in Fig. 7, for each Fkh and for each experimental condition: 703 (Fkh1 logarithmic), 974 (Fkh1 stationary), 796 (Fkh2 logarithmic) and 593 (Fkh2 stationary). Subsequently, we calculated the enrichment of functions of target genes relative to the whole genome (see Table 6).

From the analysis, we have observed that both Fkh1 and Fkh2 show an increased percentage of target genes that fall within the GO terms *Cell cycle* and *Cell division*, both in logarithmic and stationary phases, with the exception of Fkh1 in stationary phase. This result supports the earlier finding that Fkh targets are primarily cell cycle genes (Spellman *et al.*, 1998). Interestingly, we observed that a fraction of genes with a metabolic function is present among the targets. Specifically, we identified 73 and 101 metabolic enzymes targets of Fkh1 and Fkh2, respectively, in logarithmic phase, and 101 and 71 metabolic enzymes, respectively, in stationary phase. This provides a clear indication of the potential role of Fkh as hubs connecting cell cycle and metabolism.

Similarly to the calculated functional enrichment shown in Table 6, we calculated the enrichment of cell cycle-regulated target genes that peak in specific cell cycle phases (Fig. 9). When comparing the distributions of the identified target genes in our four ChIP-exo experiments to the genome-wide distribution (Kudlicki *et al.*, 2007; Rowicka *et al.*, 2007), we observed that Fkh1 targets are shifted mainly towards S, G2 and M/G1, and away from G1/P, G1/S and M, in both logarithmic and stationary phases. There are instead mixed results for G1 and G2/M. Fkh2 targets are shifted mainly towards G2, G2/M and M/G1, and away from G1, G1(P), G1/S and M, in both logarithmic and stationary phases. There are instead mixed results for S phase. Between G2 and M/G1, Fkh2 has an

Fig. 9 Distribution of the expression peak for cell cycle-regulated genes. A genome-wide dataset was compared to the ChIP-exo Fkh dataset to identify target genes that are cell cycle-regulated. The distribution of the cell cycle-regulated genes (Rowicka *et al.*, 2007) is shown in the center, whereas the other four pies show the distribution of Fkh1 and Fkh2 targets, in both logarithmic and stationary phases. The set of genes considered for the latter four pies is the subset of cell cycle-regulated genes that are retrieved as being significant at least by *one* of the four peak detection methods.

enrichment of 5.5% and 4.8% in target genes, in logarithmic and stationary phase, respectively, whereas Fkh1 of 1.6% and 0.2%, respectively, consistent with data showing that Fkh are mainly expressed during late cell cycle phases (Lee *et al.*, 2002).

In order to visualize the cell cycle-regulated target genes of Fkh1 and Fkh2 with transcription peaks across different cell cycle phases, stack plots were generated for the larger sets of retrieved significant genes, similarly to the information presented in Fig. 8. As an example, we show here the result for Fkh2 in logarithmic phase (Fig. 10). It becomes apparent that the majority of target genes, for this experimental condition, falls primarily within the GO terms *Metabolism*, followed by *Cell cycle* and *Cell division*. This evidence further supports that the Fkh-dependent transcriptional program may be also activate metabolic pathways to guarantee a timely cell cycle progression.

To investigate the network effects of the Fkh targets, these have been annotated to include the list of KEGG Pathways each gene is mapped on. As an example, we visualize the target genes of both Fkh1 and Fkh2 in central carbon metabolism, which enzymes are retrieved as significant by each of the four peak detection methods (Fig. 11). Alternatively, by using the Pathview library for R (Luo and Brouwer, 2013), the target genes may be superimposed on KEGG maps in an automated way. Strikingly, identified reliable target genes of Fkh1 in central carbon metabolism are *HXT5*, *ADH4* and *CIT2*; conversely, Fkh2 generally lacks potential reliable targets, based on our data.

Discussion

As compared to previous ChIP-based methodologies, which have been conducted in logarithmic phase, our ChIP-exo analyses were performed in two experimental conditions, logarithmic and stationary phases. In either or both conditions we observed that targets of Fkh1, but not Fkh2, are mainly found in metabolic processes (see Fig. 11), with a substantial number of metabolic enzymes (see Table 5 and Fig. 8). Therefore, we were interested to identify which specific KEGG Pathways are populated by the common core genes, which are retrieved as significant by each of the four peak detection methods used in this study.

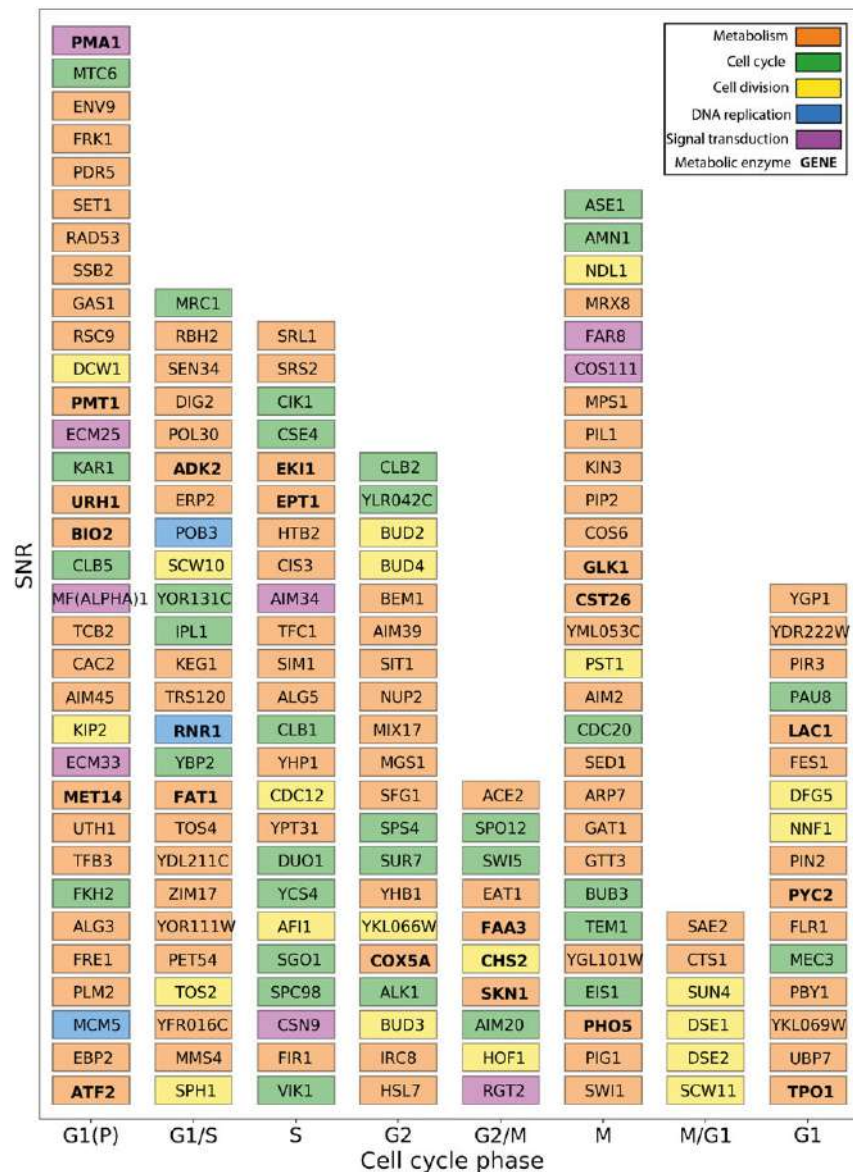

Fig. 10 Stack plot representing the Fkh2 target genes in logarithmic phase retrieved by any of the four peak detection methods. Genes are grouped according to their cell cycle phase of peak expression (Rowicka et al., 2007). Vertical ordering is based on the SNR of target genes in the maxPeak dataset. Each gene is colored according to its specific function. Genes encoding a metabolic enzyme are indicated in bold.

In Table 7 the Fkh target genes retrieved by all methods for each experimental condition were categorized according to the KEGG Pathways they occur in. A large difference between the target genes of Fkh1 and Fkh2 may be observed, due to the larger number of Fkh1 targets considered as significant. Fkh1 appears to target many different cellular processes including fatty acid metabolism, purine and pyrimidine metabolism, and central carbon metabolism. Strikingly, four Fkh1 target genes relate to the ribosome (*RPL39*, *RPL8A*, *RPS1B*, *RPS22A*). *EXG1*, a novel Fkh1 target never reported before in the literature, is a metabolic enzyme, i.e. exo-1,3-beta-glucanase, involved in cell wall beta-glucan assembly.

In the smaller set of target genes retrieved for Fkh2, only one connection with metabolism is observed. This regards the metabolic enzyme *PMA1*, plasma membrane ATPase which pumps protons out of the cell, and major regulator of cytoplasmic pH and plasma membrane potential. This gene has been previously reported as a Fkh target by a ChIP-chip study (Ostrow et al., 2014). However, the other Fkh2 target genes are functional to cell cycle and signaling (*CLN1*, *CLB2*, *SPO12*), consistently with the current view of the Fkh2 role in cell cycle progression. This evidence indicates that Fkh1 and Fkh2 appear to have divergent functions, and that these TFs may serve as hubs that integrate multi-scale regulatory networks to achieve proper timing of cell division.

The latter aspect is particularly relevant, as a number of biochemical reactions requires to be completed for a timely cell division. Coordination of these reactions requires cyclin/Cdk1 kinase complexes, which are activated upon sequential transcription of cyclin genes with a characteristic staggered behavior known as waves of cyclins (Nasmyth, 1993; Futcher, 1996). Progressive

Fig. 11 Overview of metabolic enzymes in central carbon metabolism that are targets of Fkh1 and Fkh2. Each enzyme is associated with eight squares divided in two rows (Fkh1, top row; Fkh2, bottom row) representing data analysis with four peak detection methods. Empty squares indicate that the gene was not retrieved as a significant target, whereas colored squares indicated positive evidence. A distinction between the results in logarithmic and stationary phases is visualized through the color of the squares (see the figure insert). Isoenzymes that have no available evidence in any of the four studies were neglected. In some cases, metabolic enzymes may have no associated squares when no isoenzyme is available with an experimental validation. In this latter case, we sometimes referred to a generic name of the isoenzyme, e.g., *GPM* as opposed to *GPM1*.

Table 7 Categorization according to KEGG Pathway occurrence of Fkh target genes retrieved to be significant by all four peak detection methods. Genes encoding a metabolic enzyme are indicated in bold. Genes that have not previously been observed as Fkh targets in previous ChIP studies (MacIsaac *et al.*, 2006; Hu *et al.*, 2007; Venters *et al.*, 2011; Ostrow *et al.*, 2014) are indicated in red color. The KEGG Pathways listed are not complete, but rather a representative subset of pathways that contain at least one of the Fkh target genes

<i>Kegg pathways</i>	<i>Fkh1 logarithmic</i>	<i>Fkh1 stationary</i>	<i>Fkh2 logarithmic</i>	<i>Fkh2 stationary</i>
Cell cycle – Yeast	BRN1, ESP1, TEM1	BRN1, TEM1, YCS4	CLB2	CLB2, CLN1, SPO12
MAPK signaling pathway – Yeast		MKK2	CLB2	CLB2, CLN1
Meiosis – Yeast	ESP1	HXT5, SGO1		SPO12
Citrate cycle (TCA cycle)		CIT2		
Glycolysis/Gluconeogenesis		ADH4		
Glutathione metabolism	RNR1	RNR1		
Oxidative phosphorylation		PMA1	PMA1	
Starch and sucrose metabolism	EXG1			
Mitophagy – Yeast		MKK2		
Ribosome	RPS1B	RPL39, RPL8A, RPS1B, RPS22A		
Purine metabolism	RNR1	RNR1		
Pyrimidine metabolism	RNR1	RNR1		
Terpenoid backbone biosynthesis	IDI1	IDI1		IDI1
Endocytosis		YPT31		
N-Glycan biosynthesis	ALG5	ALG5		
Fatty acid degradation		ADH4, DIT2		
RNA degradation		EDC3		
Proteasome		RPN10, RPN11		

oscillations of cyclin levels, thereby of cyclin/Cdk1 activity, ensure a robust timing of cell cycle progression and of transcriptional regulation. Fkh modulate transcription of cyclin genes in late cell cycle phases (Breedon, 2000; Jorgensen and Tyers, 2000), in particular of Clb2 and Clb3 (Koranda *et al.*, 2000; Kumar *et al.*, 2000; Pic *et al.*, 2000; Reynolds *et al.*, 2003; Linke *et al.*, 2017). Considering the relevance of Fkh in the progressive activation of the cyclin/Cdk1 complexes, we have explored the relevance of our ChIP-exo findings for Fkh1 and Fkh2 on cell cycle dynamics (Fig. 12).

In Fig. 12(A) the regulatory cascade driving cell cycle progression is shown: In G1 phase, the cyclin Cln2 (and Cln1), together with the kinase Cdk1, inhibits the cyclin/Cdk1 inhibitor Sic1. When Clb5/Cdk1 is released from Sic1 inhibition, it promotes DNA duplication in S phase. Consequently, a Clb/Cdk1 cascade is activated, involving waves of Clb5, Clb3 and Clb2 cyclins (all bound to Cdk1). In Fig. 12(B) the evidence of Fkh binding at promoters of target genes is highlighted in the Clb/Cdk1 cascade. In our ChIP-exo study, CLB2 appears to be the major target of Fkh2, as reported (Sherriff *et al.*, 2007; Reynolds *et al.*, 2003; Pic *et al.*, 2000; Kumar *et al.*, 2000; Koranda *et al.*, 2000; Hollenhorst *et al.*, 2000, 2001), in both logarithmic and stationary phases. SWI5 is also confirmed to be Fkh2 target (Zhu *et al.*, 2000; Pic *et al.*, 2000; Kumar *et al.*, 2000) as well as FKH2 (although only when using the loessPeak peak detection method), as reported by ChIP-chip and ChIP-seq, genome-wide studies (Venters *et al.*, 2011; Ostrow *et al.*, 2014; MacIsaac *et al.*, 2006).

In addition, our findings of FKH2 being target of Fkh1 and of CLB5 being target of Fkh2 are supported by a previous ChIP-chip study (Ostrow *et al.*, 2014). An interesting scenario regards the CLB3 gene. Fkh2 binding to CLB3 promoter was shown by a ChIP-chip study (Ostrow *et al.*, 2014). Furthermore, we have recently demonstrated that Fkh2 binds to the CLB3 promoter and regulates Clb3 expression, thus synchronizing the temporal expression of mitotic CLB genes (Linke *et al.*, 2017). However, in our ChIP-exo data for Fkh2, CLB3 has a SNR below threshold in stationary phase and it shows no signal in logarithmic phase when using the OL7 DNA strand approach. Interestingly, when the maxPeak detection method is used (with either AD7 or AD10), SNR values between ~0.62–1 were observed for the binding of Fkh1 and Fkh2 in both logarithmic and stationary phases, whereas using the loessPeak method with AD7 for CLB3 results in a SNR=1.003 (above noise but not above stringent threshold) for the binding of Fkh1 in stationary phase. Thus, although the SNR values indicate relatively low levels of binding of Fkh to the CLB3 promoter, we can conclude that CLB3 identification as target is sensitive to the DNA strand approach used. This specific case indicates the possible limitation of the peak detection methods when analyzing ChIP-exo data, which are not able to retrieve CLB3 although a positive evidence from an independent experimental validation exists.

Further analyses are required in order to validate the connection between Fkh and a number of metabolic pathways, and to investigate the specific role of Fkh in the Clb/Cdk1 cascade. However, our findings highlight possible novel regulatory mechanisms contributing to cell's viability, which impact on proper cell cycle dynamics. Thus, our study provides evidence of the role of Fkh as hubs connecting multi-scale cellular networks in the budding yeast cell.

Future Directions

The study that we have presented highlights the divergence in retrieving ChIP data by using a number of data analysis methods, and stimulates further research to (i) identify the more stable method(s), (ii) investigate in depth the advantages and shortcomings of each method, and (iii) measure the accuracy of the data analysis methods with regard to identifying functional targets.

Fig. 12 Fkh1 and Fkh2 target genes in the molecular cascade regulating dynamics of cell cycle progression. (A) Molecular players driving cell cycle progression (see text for details). (B) Overview of cell cycle regulators that are Fkh targets. The transcription factors *SWI4*, *SWI6*, *MPB1*, *SWI5* and *FKH2* are shown within rectangles. Genes without associated rectangles were not identified as significant Fkh targets in the various dataset.

Closing Remarks

Various ChIP-based methodologies exist, with ChIP-exo being the newest instantiation. In this study, we have presented the main differences between ChIP-exo and currently in-use ChIP techniques, and discussed two existing (GEM and MACE) and two novel (maxPeak and loessPeak) methods for analyzing ChIP-exo data. We have described a pipeline to be followed when analyzing the data, and applied it to two Forkhead (Fkh) transcription factors (Fkh1 and Fkh2) that regulate cell division in budding yeast. The result of our analysis indicates a large diversity of the target genes retrieved by the four methods. This may be explained, in part, by failure of the existing algorithms (GEM and MACE) to properly analyze the data considered here, and may point to the fact that these approaches might be less reliable when the number of high-quality peaks is relatively low. However, importantly, a small common set of retrieved target genes exists, pointing to an accurate, reliable output that is insensitive to the method used.

In this study, we have also highlighted how to integrate ChIP data with existing literature data from a number of databases containing information of genes in budding yeast, such as functional annotation, localization, abundance, and both timing and cell cycle phase of peak occurrence of RNA transcript levels. This integration has been made possible through GEMMER, a web-based visualization tool that we have recently developed.

Altogether, we have shown that our pipeline of analyzing ChIP data and integrating these with literature information allows for predicting and understanding the function of transcription factors in a multi-scale, networked, cellular system.

Author Contributions

M.B. conceived and designed the study. P.H., T.D.G.A.M., J.N. and M.B. designed the experimental analysis, which was performed by P.H.. M.B. and T.D.G.A.M. designed the computational analysis, which was performed by T.D.G.A.M.. T.D.G.A.M. and M.B. analyzed the data. M.B. provided the biological interpretation of data. P.H., T.D.G.A.M. and M.B. wrote the paper, with contribution from J.N.. M.B. provided scientific leadership and supervised the study. Petter Holland and Thierry DGA Mondeel contributed equally to this work.

Introduction

The human body is made up of a combination of specialized biological systems with specific functions. These body systems represent groups of organs, tissues, and cells that act together to perform various tasks for growth, reproduction, and survival of the body. Some organs may be part of more than one body system, if they serve more than one function. The systems work and interact with each other to form a functioning human body. The human body system comprises the skeletal system (bones, cartilage, ligaments), muscular system (cardiac or heart muscle, skeletal muscle, smooth muscle, tendons), nervous system (brain, spinal cord, nerves), respiratory system (trachea, larynx, pharynx, lungs), lymphatic system (lymph nodes, lymph vessels), immune system (bone marrow, spleen, white blood cells), endocrine system (pituitary gland, hypothalamus, adrenal glands, thyroid, parathyroids, pancreas, ovaries, testes), cardiovascular or circulatory system (heart, blood vessels, blood), digestive or excretory system (esophagus, stomach, small intestine, large intestine), urinary or renal system (kidneys, urinary bladder), integumentary or exocrine system (skin, hair, nails), and reproductive system (female: uterus, vagina, fallopian tubes, ovaries; male: penis, testes, seminal vesicles) (McDowell, 2010; Taylor, 2017). Although these body systems are all very different, they do have one thing in common, of which all of them begin with cells. During the process of cellular differentiation, a cell changes from one cell type to another with specialized function forming tissues and organs. Different cell types express characteristic sets of proteins that are encoded by respective genes within a cell's DNA (Slack, 2013).

Cells can dynamically access and translate specific information through gene expression by selectively switching on and off particular genes. In the selected genes, the information encoded is transcribed into RNA molecules, which consequently can be translated into proteins or can be directly used to control gene expression (Finotello and Di Camillo, 2015). The investigation and analysis of any individual dysregulations occurring within the genomic, transcriptomic, proteomic, and metabolomic levels could utilize advanced high-throughput technologies (Likić *et al.*, 2010; Ayers and Day 2015; Krauss *et al.*, 2017).

The transcriptome is a set of all RNA transcripts existing in a cell or tissue at a certain point of time under specific conditions (Sirri *et al.*, 2008). The transcriptome encompasses multiple types of coding and noncoding RNA species. Thus, transcriptomic study is essential to identify the current state of the cells and fundamental pathogenic mechanisms of diseases. In addition, differential gene expression study facilitates the comparison of gene expression profiles from different cells and conditions to characterize genes that are responsible in the determination of phenotypes. For example, the comparison of healthy versus diseased cells can present new insights on genetic aspects involved in pathology (Finotello and Di Camillo, 2015). Previously, microarray has been the most important and commonly used method for transcriptome analysis (Baldi and Hatfield, 2002), however in recent years, high-throughput RNA sequencing (RNA-Seq) has become a powerful alternative approach for transcriptome profiling studies. RNA-Seq is able to qualitatively and quantitatively investigate any RNA molecules including messenger RNAs (mRNAs), long noncoding RNAs (lncRNAs), microRNAs (miRNAs), and small interfering RNAs (siRNA) (Dong and Chen, 2013, Kukurba and Montgomery, 2015).

The immune system is one of the most complex body systems that the human has. The immune system comprises the innate and the adaptive systems. Monocytes, a type of leukocyte or white blood cells, are key elements of the innate immune-mediated processes that become the first line of defense response against pathogens (Janeway, 2001). They can differentiate into macrophages and myeloid lineage dendritic cells. They are mononuclear cells and play a central role in the clearance of microbial infections and cellular debris, secretion of immunoregulatory bioactive factors including interleukins, interferons, chemokines, and growth factors, and control of cancer progression (Kraft-Terry and Gendelman, 2011).

Recent studies have applied RNA-Seq technology for transcriptome profiling of several tissues and cell types such as endometrium (Zieba *et al.*, 2015), spleen (Dang *et al.*, 2016), T cells (Mitchell *et al.*, 2015), B cells (Toung *et al.*, 2011), and macrophages (Beyer *et al.*, 2012). In addition, by using the RNA-Seq approach, the global gene transcription changes that occur during the differentiation of monocyte to macrophage have been reported (Ancuta *et al.*, 2009; Dong *et al.*, 2013; Ziegler-Heitbrock *et al.*, 2010). Furthermore, the RNA-Seq data are valuable for postgenomic study leading to the development of diagnostic and therapeutic applications for precision medicine. Recently, Fuchs *et al.* (2016) established an integrative tool for postgenomic data analysis utilizing next-generation sequencing, RNA-Seq, and microarray data. However, there is limited or no data exist on the genome-wide transcriptome expression profile of human primary monocytes under healthy and disease states.

We have used bioinformatics approaches to catalogue the entire transcriptome of primary monocytes from healthy subjects using deep polyadenylated (Poly(A) +) paired-end RNA sequencing (RNA-Seq) technique. Firstly, we integrated this dataset with other publicly available RNA-Seq datasets for human monocytes to provide a comprehensive gene reference catalogue of human primary monocytes (Mirsafian *et al.*, 2016b). The reference gene catalogue of immune cells based on their transcriptome expression profiles would be useful for immune-related research, particularly for understanding disease states, pathogenesis, and developing therapeutic biomarkers. As a second step, we characterized long noncoding RNAs (lncRNAs) in human monocytes and

Fig. 1 Schematic representation of workflow to generate the gene catalogue of primary monocytes from healthy subjects.

identified unannotated lncRNAs that were not yet annotated in the public databases, of which this could facilitate future experimental studies to understand the functions of these molecules in the innate immune system (Mirsafian *et al.*, 2016a).

As an example, we present the analysis of deep RNA-Seq datasets of primary monocytes of patients with X-linked agammaglobulinemia (XLA), which is a rare X-linked genetic disorder that affects the male (Mirsafian *et al.*, 2017). XLA is caused by mutations in gene coding for *BTK* (Bruton's tyrosine kinase) located in the Xq21.3-q22 region, which is essential for B cell development and function (Vetrie *et al.*, 1993). XLA disorder is characterized by few or absent of peripheral B cells leading to a decrease in all serum immunoglobulin levels and recurrent infections with encapsulated bacteria and enteroviruses (Ochs and Smith, 1996). The expression of *BTK* is not limited to B cells. It is also expressed in other immune cells such as NK cells (Bao *et al.*, 2012), neutrophils (Honda *et al.*, 2012), and monocytes/macrophages (Koprulu and Ellmeier, 2009). It is well known that *BTK* mutations affected B cell development and functions in XLA patients (Lee *et al.*, 2010; Mohamed *et al.*, 2009; Ochs and Smith, 1996). However, the effect of *BTK* deficiency in primary monocytes of XLA patients is not fully understood and there is no or limited data available on transcriptome profiles of primary monocytes from XLA patients. Moreover, despite the evidence for a role of lncRNAs in the immune system regulation (Derrien *et al.*, 2012; Karapetyan *et al.*, 2013; Guttman *et al.*, 2009), the functions of lncRNAs in primary monocytes of XLA have not been studied yet. Through this study, a comparative gene expression analysis of primary monocytes was conducted between RNA-Seq datasets of XLA patients and healthy male subjects to look into the possible differences in expression patterns of protein-coding genes and lncRNAs in XLA patients compared to healthy individuals, which may affect the function of primary monocytes in these patients. The high-resolution genome-wide transcriptome expression profile of primary monocytes based on the RNA-Seq approach would provide a better understanding of monocytes' characterization and function in healthy and XLA states. It also assists the detailed analyses of innate immune system abnormalities and novel pathomechanisms concerning XLA.

Fig. 2 Schematic representation of workflow to profile the lncRNAs expression landscape of primary monocytes from healthy subjects.

Step 1: Techniques for Cell Preparation and Transcriptome Profiling

The techniques used for monocyte isolation and transcriptome profiling have been described in [Mirsafian et al. \(2016a,b, 2017\)](#). Briefly, the peripheral blood samples from 6 healthy individuals (3 male and 3 female) and 3 male patients with XLA were collected. The classical monocytes (CD14 + + CD16 –) were isolated from peripheral blood mononuclear cells, which are a mixed population of different cell types including lymphocytes, monocytes, and macrophages) using a negative selection technique. Using this method, the nonmonocyte cells including T cells, B cells, dendritic cells, NK cells, and basophils were indirectly magnetically labeled and the untouched monocytes were then isolated by depletion of the magnetically labeled cells. The purity of isolated monocytes from all samples were checked separately by flow cytometry analysis and were found to be >90% for all samples. The total RNA was extracted from monocytes and the quality, quantity, and integrity of the extracted RNA from all samples were checked separately. The purified RNA was used to perform deep poly(A) + paired-end RNA sequencing. All the reads were mapped to the reference genome (Ensembl GRCH38.79) and assembled into a transcriptome. The transcripts were reconstructed for all aligned reads separately and then merged together to form a single nonredundant set of transcripts. The abundance of assembled transcripts was estimated using fragments per kilobase of exon per million fragments mapped value. Detailed information on the bioinformatics analysis workflows and pipeline is described in [Figs. 1–3](#).

Fig. 3 Schematic representation of workflow of analysis of RNA-Seq dataset of primary monocytes from XLA patients.

Step 2: Establishment of a Reference Gene Catalog of Human Primary Monocytes

RNA-Seq datasets from 6 healthy individuals were integrated with other publicly available RNA-Seq datasets for monocytes. Based on these datasets, we were able to capture most of the genes transcribed in human monocytes including: 11,994 protein-coding genes, 5558 noncoding genes, 2820 pseudogenes, and 7034 putative novel transcripts. The summary of identified genes and transcripts with regard to their biotype is presented in [Table 1](#).

The functional analysis of identified protein-coding genes expressed in monocytes revealed that highly expressed genes were mainly involved in several processes belonging to the immune system while the moderately expressed genes and lowly expressed genes were mainly involved in metabolic processes and biological regulations ([Fig. 4](#)). These results showed that genes within a particular process are expressed at similar levels, which is in agreement with a previous study ([Toung et al., 2011](#)). It has been reported that in B cells, the high-expressing genes were involved in translation, RNA processing, and splicing transcription, and the medium- and low-expressing genes were related to cell adhesion and ion transport and transcription, respectively ([Toung et al., 2011](#)).

Using these datasets, the expression pattern of 1155 transcription factors (TFs) in human primary monocytes were also profiled. TFs are key molecules that control gene transcriptions ([Vaquerizas et al., 2009](#)). Over the past 30 years, several TFs involved in the immune system have been discovered and their mechanisms of action were studied ([Smale, 2014](#)). The interaction network between the top 20 highly expressed identified TFs with their targeted genes is presented in [Fig. 5](#).

Addition of publicly available RNA-Seq datasets for monocytes to our RNA-Seq dataset from healthy individuals also allowed us to provide a landscape of lncRNAs in human primary monocytes. Several recent studies have shown the role of lncRNAs in relation to immune regulation and their role in several autoimmune diseases like SLE ([Shi et al., 2014](#)) and rheumatoid arthritis ([Müller et al., 2014](#)). Recent studies have also indicated the possible role of lncRNA expression and its correlation to immune cells' differentiation and

Table 1 Summary of identified genes and transcripts in human monocytes

Gene biotype	Protein-coding	Noncoding			Pseudogenes	Novel

maturation (Stachurska *et al.*, 2014). However, most of the lncRNAs transcribed in the innate immune system remain unknown. From this study, the expression of 6382 lncRNAs (40% of the known lncRNAs reported in GENCODE database (version 22)) were characterized in human primary monocytes. Using a computational pipeline developed in-house, a total of 1032 unannotated lincRNAs in monocytes were identified that have not been annotated in the public databases (Mirsafian *et al.*, 2016a).

The study described above resulted in a comprehensive reference gene catalog of human primary monocytes under healthy states, which could be used as an important resource for postgenomics and system biology research on human monocytes under healthy and diseased states (Mirsafian *et al.*, 2016b).

Step 3: Comparative Analysis of Transcriptome Profile of Healthy Individuals and XLA Patients

Deep RNA-Seq approach on primary monocytes from 3 XLA patients generated approximately 477 million reads of 100 bp read length. This led to the profiles of 17,510 genes (including 11,788 protein-coding genes, 3681 noncoding genes, 2041 pseudo-genes) and 62,367 transcripts (including 58,136 annotated and 4231 novel transcripts) in the primary monocytes of XLA patients. In addition, the lncRNAs expression patterns in primary monocytes of XLA patients were analyzed and a total of 3363 annotated lncRNAs were identified. By using multistep mapping and filtering criteria, the expression of 430 potential novel lincRNAs in the patients were also identified.

A comparative analysis on gene expression profiles of primary monocytes between healthy individuals and XLA patients was performed to examine possible differences in the gene expression patterns of primary monocytes in XLA patients. The comparative analysis showed the total of 1827 DE protein-coding genes in XLA patients compared to healthy subjects. Out of 1827 DE protein-coding genes, 859 genes were upregulated and 968 genes were downregulated in XLA patients compared to the healthy subjects. Based on the GO and KEGG pathways analysis, the detailed information on the biological functions and potential mechanisms of detected DE protein-coding genes were obtained. The GO enrichment analysis showed that downregulated genes were mainly involved in regulation of immune response. Pathway analysis also revealed that downregulated genes mainly enriched in several pathways belonged to innate immune system such as "Fc gamma R-mediated phagocytosis," "Chemokine signaling pathways," "Toll like receptors signaling pathway," and "MTOR signaling pathway," which reflected the deficiencies of innate immune function in primary monocytes of XLA patients (Fig. 6).

Evidence suggests that in addition to protein-coding genes, lncRNAs can act as key regulators of various biologic processes (Clark and Mattick, 2011; Kim and Sung, 2012). The lncRNAs function via DNA–DNA, DNA–RNA, or other kinds of interactions (Satpathy and Chang, 2015). The lncRNAs dysregulated expression has been reported in many human diseases (Hrdlickova *et al.*, 2014; Wapinski and Chang, 2011). However, little is known about lncRNAs' role in XLA patients. Through the comparative analysis of lncRNA expressions in primary monocytes between XLA patients and healthy subjects, 95 DE annotated lncRNAs including 56 upregulated and 39 downregulated and 20 DE novel lncRNAs including 5 upregulated and 15 downregulated were obtained in XLA patients compared to healthy subjects.

Overall the results as presented above indicated the inclusive dysregulation of monocytes' immune functions and the increase of susceptibility to apoptosis in monocytes of XLA patients. This suggests that BTK mutations are not only affecting the B cell development and differentiation, they would be also contributing to dysregulation of innate immune system in XLA patients. This study also revealed the differentially expression patterns of lncRNAs in primary monocytes of XLA patients that would suggest the potential role of lncRNAs in regulation of immune functions in primary monocytes of XLA patients (Mirsafian *et al.*, 2017).

Fig. 6 The GO and KEGG pathway analysis of DE lncRNAs colocated genes in primary monocytes of XLA patients compared to healthy subjects. The significant GO biological process terms enriched for (a) DE annotated lncRNAs colocated genes, and (b) DE novel lncRNAs colocated genes. The number of DE lncRNAs colocated genes enriched in each GO terms is depicted above the bars in the figure. The significant KEGG pathway terms enriched for (c) DE annotated lncRNAs colocated genes, and (d) DE novel lncRNAs colocated genes. The numbers in the brackets indicated the total numbers of genes available in the KEGG database for each pathway terms. The number of identified DE lncRNAs colocated genes enriched in each KEGG pathways is depicted above the bars in the figure. Reproduced from Mirsafian, H., Ripen, A.M., Leong, W.M., *et al.*, 2017. Transcriptome profiling of monocytes from XLA patients revealed the innate immune function dysregulation due to the BTK gene expression deficiency. *Scientific Reports* 7 (1), 6836.

Conclusions

Transcriptomic data based on deep RNA-Seq approach can provide valuable information on differential gene and transcript expression patterns in specific cell types. Herein, we described the analysis of transcriptomic datasets from monocytes of the innate immune system, which resulted in a comprehensive expression profile of human primary monocytes under healthy and XLA disease states. This also includes the establishment of a reference gene catalog of human primary monocytes. A set of differentially expressed (DE) protein-coding genes and DE lncRNAs identified in XLA patients compared to the healthy individuals opens exciting and several potential avenues of research that will help us to better understand the complex pathophysiology in XLA disease. We believe that transcriptomic profiling based on the RNA-Seq approach offers significant promise towards precision medicine, systems diagnostics, immunogenomics, and the development of genomic markers as well as innovative therapeutic monitoring strategies.

Closing Remarks

The availability of high coverage and greater resolution transcriptomic datasets generated from high-throughput RNA-Seq approaches have made possible the applications of systems bioinformatics to further elucidate the functional complexity and provide better understanding of the human body systems towards advancement in healthcare and biomedical research. One of the big challenges that lie ahead is to integrate different types of “omics” datasets (i.e., multiomics datasets comprising, for example, genomics, transcriptomics, proteomics, and metabolomics data from similar or identical biological background) generated from multiomics measurement platforms in order to provide meaningful insights and in-depth understanding on how a given genotype affects the phenotypic features of a given individual through various molecular mediators as well as interaction between a genotype and the environment. We believe that as technologies mature and computational data analysis pipelines and methodologies become more robust and sophisticated, such challenges will be overcome in the very near future.

Acknowledgements

The authors acknowledged the financial support for the research on the transcriptome profiling of the monocytes using RNA-Seq approach from the UM-MOHE High Impact Research (HIR) Grant Scheme: UM.S/P/HIR/MOHE/30; Ministry of Higher Education Malaysia Fundamental Research Grant Scheme (FRGS): FP050–2016; University of Malaya Research Grant (UMRG): RP004C: 13AFR and University of Malaya PPP Postgraduate Grant: PG086–2013B. The authors would also like to thank the Director General of Health, Malaysia for supporting the work carried out by the authors on this subject.

Host-Pathogen Interactions

Introduction

"You must not fight too often with one enemy, or you will teach him all your art of war."

– Plutarch

Humanity's war against infectious disease is an epic and gruelling conflict, one which has not yet been won. In the last two centuries, advances in science and technology have turned the tide on many fronts, through the development of treatments to help the body subdue, eradicate, or prevent infections. This is a war where espionage and intelligence go a long way – the more knowledge we have about pathogens and their interactions with their respective host systems, the easier it is to find new ways of defeating them; or at the very least, subduing them. Substantial improvements made in recent decades in genomic and proteomic technology have allowed for vast amounts of data to be created. The challenge now is to find elegant and efficient methods of analysing this data to work out the fine details of host-pathogen interactions – how pathogens invade, evade, and proliferate, and the damage they do to their hosts in the process. Such information is key to the development of new therapeutics, treatment strategies, methods of diagnosis, and vaccines to prevent and mediate infection.

The field of bioinformatics has been essential in keeping up with the flood of new data in this area. Strategies for storing, handling, and analysing such data have been developed, and are continuing to be improved on. The post-genomic era has seen an explosion of databases and methodologies for investigating the different aspects of host-pathogen interactions. Each omics field has developed its own approaches to tackling the problem, through processing, analysis, and prediction. There are also current efforts to synthesise the information obtained from a variety of different omics fields to create a global approach to host-pathogen interaction determination.

This article is divided into four main sections. The first section sets up the fundamentals of host-pathogen interactions and current methods to investigate them. This includes a discussion of the terminology of pathogenesis, and the contention around how it is defined, as well as discussion of infection, and current bioinformatics tools to probe it. The second section focusses on how these fundamentals have been applied in the design of drugs and vaccines. The third section discusses the current issues and unresolved contentions surrounding host-pathogen interactions, and the role of bioinformatics in solving them. The last section deals with possible outlooks to the future, with an emphasis on open questions and areas requiring a synthesis of ideas.

Fundamentals

Defining Pathogens

Before we can begin to discuss current approaches to elucidating the details of host-pathogen interactions, we need to clarify what it is we mean by pathogens, what kinds of hosts they invade, and the nature of possible interactions between the two. Historically, as our understanding of disease and its causative agents has increased, the emphasis has shifted from an invader-centric view to a more holistic, host-invader view, where factors such as the type of host and its immune defences, as well as the interaction between the invader and the host are important to defining what a pathogen is. In the last two decades, there has been significant discussion on redefining terms; such as, pathogen, pathogenicity, and virulence; to match this equal emphasis (Casadevall and Pirofski, 1999, 2000, 2001; Methot and Alizon, 2014). These are summarised in [Table 1](#), where the common thread concerns the ability to cause damage in a particular host, and the possible extent of this damage. Such an idea makes host-pathogen interactions the centrepiece in investigating disease as they form the crucial connection between the intricate details of a pathogen and the intricate details of the host, which taken individually do not give us a good picture of disease itself.

If we take a pathogen as being something which causes damage in a host, the next questions to ask are: what kind of pathogens do we know about already, and what hosts do they infect? At present, it is useful to categorise pathogens into six types: viruses, bacteria, fungi, protozoa, parasites, and prions. Most work concerning host-pathogen interactions has been done with respect to the first four categories. The fifth category, parasites, is essentially a catch-all for infective organisms which do not fit well into any of the other categories, helminths being prominent examples. The final category, prions, is unique in that the pathogen is (in some cases hypothesised to be) a misfolded protein, rather than an organism. Key representatives of each category (with humans as hosts) are given in [Table 2](#), along with the diseases they cause.

Not every possible invasive species is pathogenic in humans – how pathogenic a particular organism is depends strongly on the host it is trying to invade. The defences that must be evaded and the conditions that must be adapted to vary widely in their details from host to host, and will often require a unique set of machinery. Therefore, most pathogens evolve to target a particular host almost exclusively. It is important to recognise that interactions pathogens may have with non-human hosts are hints rather than concrete answers as to their interactions with humans. However, there are several good reasons to investigate pathogens in organisms aside from humans. Firstly, the study of pathogenesis in model organisms is often more achievable than in humans, due to well-established methods and comprehensive databases. Organisms; such as, the nematode *Caenorhabditis elegans* (Kurcz and

Table 1 Definitions of common terms associated with host-pathogen interactions, emphasising the dual sources of pathogenicity – pathogen and host

Term	Definition (as per Casadevall and Pirofski, 1999)
Pathogen	A microbe capable of causing host damage; host damage can result from either direct microbial action or the host immune response
Pathogenicity	The capacity of a microbe to cause damage in a host
Virulence	The relative capacity of a microbe to cause damage in a host
Virulence factor	A component of a pathogen that damages the host; this can include components essential for viability

Casadevall, A., Pirofski, L.A., 1999. Host-pathogen interactions: Redefining the basic concepts of virulence and pathogenicity. *Infection and Immunity* 67(8), 3703–3713.

Table 2 Common examples of each type of pathogen in humans, including the corresponding diseases they cause

Pathogen Type	Pathogens	Diseases
Viruses	Hepatitis (A-E) virus	Hepatitis (A-E)
	Herpes simplex virus (1–2)	Herpes
	Human immunodeficiency virus	HIV/AIDS
	Influenza virus A	Influenza
	Measles virus	Measles
	Dengue virus	Dengue fever
	Varicella zoster virus	Chicken pox
	Zika virus	Zika fever
Bacteria	<i>Clostridium tetani</i>	Tetanus
	<i>Vibrio cholerae</i>	Cholera
	<i>Mycobacterium tuberculosis</i>	Tuberculosis
	<i>Streptococcus pneumoniae</i>	Pneumonia
	<i>Salmonella</i> Typhi	Typhoid
	<i>Salmonella</i> Typhimurium	Gastroenteritis
	<i>Borrelia burgdorferi</i>	Lyme disease
	<i>Treponema pallidum</i>	Syphilis
Fungi	<i>Yersinia pestis</i>	Plague
	<i>Aspergillus fumigatus</i>	Aspergillosis
	<i>Candida albicans</i>	Candidiasis (thrush)
	<i>Trichophyton rubrum</i>	Ringworm
	<i>Histoplasma capsulatum</i>	Histoplasmosis
	<i>Cryptococcus neoformans</i>	Cryptococcus and fungal meningitis
	<i>Plasmodium falciparum</i>	Malaria
	<i>Entamoeba histolytica</i>	Amoebic dysentery
Protozoa	<i>Trypanosoma brucei</i>	African sleeping sickness
	<i>Giardia lamblia</i>	Giardiasis (Beaver fever)
	<i>Ancylostoma duodenale</i>	Hookworm
	<i>Schistosoma mansoni</i>	Schistosomiasis (Swamp fever)
	<i>Taenia solium</i>	Tapeworm infection
	CJD prion	Creutzfeldt-Jakob disease
	vCJD prion	Variant Creutzfeldt-Jakob disease
	Kuru prion	Kuru

Ewbank, 2000), the fruit fly *Drosophila melanogaster* (Vodovar *et al.*, 2004), and the zebrafish *Danio rerio* (Meijer and Spaink, 2011; Tobin *et al.*, 2012); are significant non-human hosts in the study of host-pathogen interactions. Secondly, by analysing data obtained from other host organisms, we can investigate tools that pathogens have to invade, evade, and proliferate, which provide leads to finding key interactions with humans. Thirdly, animal and plant diseases are economically and ecologically significant due to their role in food production and conservation. Lastly, the possibility of diseases undergoing a zoonotic jump from animals to humans means the study of animal diseases is of preventative significance (Baigent and McCauley, 2003).

Due to the current directions of the field, as well as pressing medical relevance, the primary focus of the current chapter will be on human hosts and their interactions with pathogens, with only secondary mentions of non-human hosts.

Stages of Infection

In broad terms, there are four stages of host-pathogen interactions: the pathogen invading the host system, the pathogen evading the host system's defences, the pathogen proliferating in the host system, and the host system's immune response to the invader.

Different pathogens will possibly have different machinery at each stage, with some mechanisms developing in response to very specific host system defences. The four stages are not disjoint; there is some overlap between them, with some stages being more infectious for certain pathogens than others. An overview of our current knowledge of host-pathogen interactions at each stage is provided below; state-of-the-art methods used to gain knowledge in these areas are discussed in more detail in the next section.

Invading the host system

Initial infection can occur *via* a number of pathways – the pathogen may enter the body through the mouth or nose, the bloodstream (possibly through a contaminated needle), or through mucosal membranes, as well as other more specialised means. However, once the pathogen has entered, it must interact with the host cells in order to remain within the host and continue its invasion. The form this interaction takes depends on the type of pathogen. Viral pathogens invade host cells by merging their envelope with the membrane of either a cell or an endosome. For other pathogens, including Gram-negative bacteria, specialised protein secretion systems are used to release so-called effector proteins into host cells which trigger a particular response mechanism in the host, allowing the invader to migrate to a preferable environment. Such secretion and injection machinery is not always required, especially in fungal pathogens. Instead, effector proteins are expressed on the surface of the invader, and interact with host cell receptors. The host's response to these proteins typically allows the pathogen to invade deeper into the host system.

In most cases, viral pathogens invade by merging with the host cell membrane itself. This is aided through the use of fusion proteins provided by the virus, promoting attachment and fusing of the host and pathogen membranes. In general, the fusion proteins used by each type of virus are distinct, meaning that vaccines and drug therapies must be designed specifically for each type (Cohen, 2016).

So far, six distinct secretion systems have been discovered in Gram-negative bacteria: Type I (Welch *et al.*, 1981), Type II (d'Enfert *et al.*, 1987), Type III (Galán and Curtiss, 1989), Type IV (Kuldau *et al.*, 1990), Type V (Pohlner *et al.*, 1987), and Type VI (Pukatzki *et al.*, 2006; Mougous *et al.*, 2006). In mycobacteria, there is the Type VII secretory system, also known as the ESX system (Stanley *et al.*, 2003). In general, these systems act as injectors, transporting effector proteins from the invading pathogen to the host cell. The particular proteins secreted by each type of system are still being determined; recent methods for such investigations are discussed in Section "Bioinformatic Methods of Discovery". The details of the delivery mechanisms are also still being discovered; for an in-depth discussion of our current knowledge of secretion system machinery itself, see Further Reading 1 (Costa *et al.*, 2015).

Fungal invasion mechanisms in many ways lie between those of viruses and bacteria. Instead of effector proteins being injected into the host cell, they are only located on the hyphal surface of the pathogen. These are then presented to host cell receptors, which induce a change that the pathogen can exploit. In the case of *Candida albicans*, the changes can lead to induced endocytosis or cellular uptake of the pathogen, as well as active penetration, where the pathogen exploits the interaction to penetrate the epithelial lining (Yang *et al.*, 2014).

As most known invasion mechanisms proceed *via* protein-protein interactions on the surface of cells, glycosylation plays a significant role in determining pathogenicity (Hooper and Gordon, 2001). If the glycosylation of surface proteins in one part of the body is not compatible with the pathogen, the interaction is weakened and invasion is also significantly reduced. Either the presence or the absence of glycosylation can be essential to pathogenicity depending on the type of invader, as some effector proteins selectively bind to certain glycoproteins (Hooper and Gordon, 2001).

Evading the host system

Once the pathogen has successfully gained a foothold inside the host system, it will in most cases attempt to evade the host's defences in order to survive. There are a number of mechanisms through which pathogens try to evade defence systems, including affecting essential pathways in the host to increase or decrease defence activity, inhibiting macrophage activity, and sabotaging crosstalk in pathways using miRNA and short linear motifs (SLiMs).

Immune responses are triggered through a variety of essential pathways, resulting in the activation of both intra- and extra-cellular mechanisms to tackle the invader. In order to evade these mechanisms, pathogens have adapted to target specific pathways in order to optimise their survival chances. One such target is the NF- κ B pathway, which plays a role in the regulation of apoptosis (Tato and Hunter, 2002). A variety of bacterial, viral and parasitic pathogens have all been found to attack the NF- κ B pathway, either through activation or inhibition (Rahman and McFadden, 2011), and it is therefore crucial to early infection. Other possible targets for pathogens are so-called 'hub' proteins, which connect with a variety of signal pathways (Dyer *et al.*, 2008), in particular in the case of the Epstein-Barr virus (Calderwood *et al.*, 2007).

Upon activating the immune defences of the host, the invader is in most cases hunted down and consumed by the macrophage. Therefore, many pathogens attempt to avoid detection by the macrophage, or inhibit its activity. In the case of *Mycobacterium tuberculosis*, this is possibly achieved by inhibiting interleukin-12 production, in turn inhibiting macrophage activation (Nau *et al.*, 2002). In the case of viruses, between 26 and 37 HIV-1 proteins have been associated with monocyte-derived macrophages (Chertova *et al.*, 2006), indicating this is a significant target of the host defence system.

Invaders also attempt to sabotage the molecular crosstalk of the host *via* microRNA regulation (Scaria *et al.*, 2007). This is particularly the case for viral pathogens, where the invading microRNA can modulate the expression of viral and antiviral genes, therefore playing an essential role in staying undetected in the host (Ghosh *et al.*, 2009). Fungal pathogens have also been shown to suppress immunity in plants by hijacking RNA interference pathways using sRNAs (Weiberg *et al.*, 2013).

Another possible avenue for sabotage is through protein-protein interaction, by use of short linear motifs (SLiMs). By mimicking the protein interactions of the host, the pathogen can regulate essential pathways to its benefit (Via *et al.*, 2015). There have been recent attempts to predict such mimicry in the HIV-1-human interaction using disorder prediction algorithms (Becerra *et al.*, 2017).

Proliferating in the host system

It is not normally sufficient for a pathogen to invade and evade a host; there must be some benefit to the pathogen once it has taken root in the host system. This is largely due to adaptations by pathogens to more easily proliferate in the host system, rather than on their own. In many pathogens, there is a substantial difference in the number of genes required to survive inside the host as opposed to outside, with the mechanisms for proliferating inside the host requiring significantly less genes (Raghunathan *et al.*, 2009). The methods through which the pathogen co-opts the host machinery also depend on the type of pathogen. Host factors, or proteins produced by the host which end up playing a significant role in the proliferation of the pathogen, also tend to be significant players in establishing pathogen replication.

The hijacking of host cells by viruses (Davey *et al.*, 2011) and bacteria (Bhavsar *et al.*, 2007) is a key part of the pathogen not only surviving, but thriving in the host. How a particular pathogen has adapted to exploit the inherent machinery of the host is often a significant difference between pathogen types. This is particularly essential in the case of viruses, where the extremely compact nature of their genome requires the host cell machinery for replication. Indeed, the relationship between viruses and their host is so intimate that the host can act as vehicle for gene transfer between viruses (Rappoport and Linial, 2012).

The host can also unknowingly provide essential components for the replication and survival of pathogens. Such host factors are the subject of intense study as possible drug targets which do not depend as heavily on the specific genetic details of the invading pathogen. As many as 295 human host factors have been identified as necessary in the replication of the influenza virus (König *et al.*, 2010), while 213 host factors have been associated with HIV-1 replication (Brass *et al.*, 2008).

Immune control of invader

An invader is unlikely to escape the immune response of the host indefinitely; therefore, at some point the host will seek to control the threat. What methods does a host have at its disposal to control the pathogen? At the fundamental level, the host can trigger gene pathways to create an immune response to destroy the invader. Within a cell, autophagy can be used to remove the threat. Extracellularly, the use of dendritic cells, especially in the intestine, is important in suppressing pathogens. In many immune processes, iron regulation is essential and must be carefully controlled. Therefore, all of the above processes are potential targets for pathogens to prevent immune control and subsequent destruction.

The initial response of a host to the detection of invaders is the activation of immune signalling cascades. Depending on the type of pathogen, particular genes may also be highly expressed; these genes are significant both as targets for pathogens, as well as targets for possible drug therapies in activating the immune system to combat invaders. In the particular case of *Mycobacterium tuberculosis* infection in a mouse host, 67 genes were identified as being highly expressed in immune-competent mice, but not in immune-compromised mice (Talaat *et al.*, 2004). This suggests that these 67 genes are significant in combatting tuberculosis infection in mice, and give potential leads to similar genes in humans.

Autophagy is an intracellular lysosomal degradation process which is usually used to break down damaged organelles and other hazardous cellular products. It is also essential to the degradation of *Mycobacterium tuberculosis* during infection (Vergne *et al.*, 2006). However, the precise mechanisms by which *Mycobacterium tuberculosis* does or does not avoid autophagy in the macrophage is still under discussion, with strong indications that microRNA plays a role (Kim *et al.*, 2017).

Dendritic cells are antigen-presenting cells which act as regulators of both the innate and adaptive immune systems (Kelsall *et al.*, 2002). While they are essential in generating an appropriate immune response from the host, they are not immune to manipulation by invaders. In particular, dendritic cells are able to migrate from sites of infection to the lymph nodes, in turn activating T cells. However, this also allows for the possible migration of pathogens around the body; in the event of build-up of migratory dendritic cells, this also creates persistent inflammatory responses (Worbs *et al.*, 2017). For a thorough discussion of the role of dendritic cells in health and disease, see Worbs *et al.* (2017).

Iron is an essential part of both the responses of hosts to invaders, as well as pathogen survival. During infection, host responses tend to withdraw iron from pathogen sites; however, pathogens have developed methods of harvesting iron from other sources, such as heme, transferrin, ferritin and lactoferrin (Doherty, 2007). Therefore, in iron-deficient patients presenting infections such as tuberculosis, the decision to supplement iron must be weighed against aiding the pathogen (Doherty, 2007).

Bioinformatic Methods of Discovery

Bioinformatics has played, and will continue to play, an extremely large role in determining host-pathogen interactions. In the post-genomic scientific landscape, the emphasis on 'big data' is extremely high; methods which can fully utilise the wealth of data available have an edge on traditional, small-sample methods. Therefore, there has been more recent emphasis on machine learning and network methods in predicting and analysing the connections between hosts and pathogens. However, there is also still a strong contribution from more biochemistry-based approaches which utilise homology and structure to predict novel host-pathogen interactions.

The analysis of current methods in bioinformatics is divided into two broad, and by no means strictly exclusive, categories: biological methods, which arise from traditional biologically-inspired methodologies informed by structure and homology; and computational methods, which arise from more computationally-inspired methodologies such as network analysis and machine learning.

Biological methods

Computational methods of predicting host-pathogen interactions can make significant use of the structural information of proteins, as well as previously known interactions with other proteins, in order to narrow results. This can be done by searching for homologous proteins in the pathogen or host which may also interact with known proteins (so-called interologues). Alternatively, it can be done by comparing structural features such as domains or motifs to those present in known interactions. There is also the possibility of using the 3D structural information of proteins, such as those with known crystal structures, to inform analysis methods. A more detailed recent review of structure-based methods can be found in Further Reading 2 (Mariano and Wuchty, 2017), but highlights are presented in this section to capture the prevailing methods.

Homology-based prediction methods only work well in situations where there is a large degree of similarity or evolutionary conservation between the organisms or proteins under discussion. However, this is often the case in related pathogens, for example between different bacterial serotypes. Such an approach has been taken in analysing malaria in the *Homo sapiens-Plasmodium falciparum* host-pathogen pairing (Krishnadev and Srinivasan, 2008). The method analyses the genomic data of both organisms, and identifies homologous proteins with known protein-protein interactions. These are then compared between the two organisms to determine the likelihood of any protein-protein host-pathogen interactions occurring. A significant problem with homology-based methods is the high false positive rate (Mariano and Wuchty, 2017) – protein pairs identified may not be expressed at the same time, in the same location, and may not ever come into contact, *let alone* interact. Therefore, successful homology approaches require filters that account for these criteria, such as the use of random forest classifiers in again analysing the *Homo sapiens-Plasmodium falciparum* pairing (Dyer *et al.*, 2007; Wuchty, 2011). There has also been prediction of protein-protein interactions through comparative modelling (Davis *et al.*, 2007), which was applied across 10 pathogens, including species of *Mycobacterium*.

The analysis of smaller sections of candidate proteins from either the host or the pathogen can also provide good indications of host-pathogen interactions. By determining the domains of these proteins, and comparing to databases of known domain-domain interactions, lists of possible candidates can be narrowed down (König *et al.*, 2008). There is also the potential for domain-motif and motif-motif interactions through smaller sections of the protein. Such short linear motifs or SLiMs have also been used to improve the accuracy of predictive methods (Becerra *et al.*, 2017), and in HIV-1 (Via *et al.*, 2015). Conserved peptide motifs in human proteins have been used to predict possible human-HIV-1 protein-protein interactions (Evans *et al.*, 2009).

Computational methods

In order to find new host-pathogen interactions, a vast pool of data must be processed, sorting good predictors in the data from bad predictors, and weighing up their contributions to give an overall predictive strategy. This is precisely the domain in which machine learning and network analysis excel. There are two possible approaches within machine learning to solve such problems concerning host-pathogen interactions. Supervised learning is the most prevalent set of methods in analysing host-pathogen interactions, wherein possible predictors are identified beforehand, leaving their weights and relative importance to be determined by a training set of data. This is because in many cases we think we know what features we want to analyse through, and like to rely on curated datasets. For example, some common chosen features include gene expression profiles, gene ontology annotations, topological properties of known proteins, functional motifs and post-translational modifications. However, semi-supervised learning methods are also gaining traction through the prevalence of partially-labelled datasets, allowing other features to be identified throughout the model construction process that may not have been identified as inputs beforehand. Due to the highly interdependent nature of intracellular interactions, network analysis methods have also seen significant use, utilising the vast connections and possible interactions between proteins to identify possible intersections and new host-pathogen interactions.

Classifier-based methods have been a popular choice in identifying host-pathogen interactions, including random forest methods (Tastan *et al.*, 2009; Wuchty, 2011). In these cases, the interactions between *Homo sapiens* and HIV-1, and *Homo sapiens* and *P. falciparum*, respectively, were analysed, using appropriate feature choices in each case to encompass the most reliable known information about the pairing, such as known feature motifs, gene expression profiles, and amino acid profiles. These methods have had some success in predicting known (and recently experimentally verified) interactions, as well as previously unknown ones, with varying accuracy. Other methods, such as Naïve Bayes (Arnold *et al.*, 2009), Support Vector Machines (SVMs) (Wang *et al.*, 2011) and group lasso methods (Kshirsagar *et al.*, 2012) have also had varying levels of success in identifying known host-pathogen interactions and predicting new host-pathogen interactions from big data sets. Many of the features used across models include the amino acid profile of proteins, relative positions of residues in the structures, as well as overarching secondary features that can be identified from the primary sequence. Other methods take information such as known protein-protein interactions to predict new ones using structural similarities. Often, these models require regularizers in order to minimise the bias introduced from the biological assumption that similar proteins will interact in similar ways, which would otherwise limit the power to predict novel interactions.

Multi-task learning and semi-supervised auxiliary tasks, including multi-layer perceptron methods (supervised) and perceptron methods with partial label reference (semi-supervised), are also being used to predict novel host-pathogen interactions from current data

(Qi *et al.*, 2010; Kshirsagar *et al.*, 2013). In this case, fully labelled reference data has been used to train a (supervised) perceptron model, while partially labelled reference data has been used afterwards to improve the feature determination and weighting (semi-supervised) in the case of the *Homo sapiens*-HIV-1 host-pathogen system. Indeed, there has been significant recent emphasis on HIV-1 analysis due to the development of the HIV-1, Human protein interaction database (Fu *et al.*, 2009). Previous machine learning methods have been well-characterized and summarised (Pinney *et al.*, 2009), while more recent *in silico* approaches to *Homo sapiens*-HIV-1 protein-protein interactions have also been thoroughly reviewed (Bandyopadhyay *et al.*, 2015). Network analysis-based methods have also seen use in this area, with interactome-based network analysis of interaction between HIV-1 proteins and signal transduction pathways identifying possible alternatives around the proteins targeted by HIV-1 (Balakrishnan *et al.*, 2009).

For further details and methods of machine learning approaches, Further Reading 3 (Carvalho Leite *et al.*, 2017) has a substantial recent review of methods in this area. For a more thorough recent review of network methods, see Further Reading 4 (Pan *et al.*, 2016), as well as a review of computational systems biology methods in Further Reading 5 (Durmuş *et al.*, 2015).

Databases for Host-Pathogen Interaction

The need for comprehensive, well-curated data sources is a persistent problem in the field of bioinformatics. In some areas this has been solved through large-scale collaborative efforts, such as with the RCSB Protein Data Bank for structural data of proteins (Berman *et al.*, 2000). However, in the field of host-pathogen interactions, there is still a lot of discussion and contention over good data sources, and several curated databases to choose from, varying in the type of data, the quality, and the level of detail in the curation. This section in conjunction with Table 3, aims to provide a survey of currently available sources of large datasets related to host-pathogen interactions. The IDs provided in brackets correspond to those in the ID column of Table 3.

The PATRIC (1), ViPR (2), EuPathDB (3), VectorBase (4), and IRD (5) databases are currently funded by the National Institute of Allergy and Infectious Diseases (NIAID). PATRIC is a bacterial pathogen database which is extremely comprehensive, and has available a number of tools such as genome annotation and comparative pathway analysis. ViPR is a viral pathogen database which is also quite comprehensive in terms of its scope. EuPathDB is a eukaryotic pathogen database, including fungal pathogens, protozoal pathogens, and other parasitic pathogens. VectorBase is a database of interactions between pathogens and invertebrate vectors, such as mosquitoes. The Influenza Research Database (IRD) is a database focussed on interactions between influenza viruses and various hosts. While very specific, it is very comprehensive. VirHostNet 2.0 (6) is a virus-virus, virus-host, and host-host interaction network database. Other virus databases include VirusMentha (7), ViralZone (8), and ViTa (9). Specific databases for particular viruses also exist, such as the HIV-1, Human Protein

Interaction Database (14) and HIV Database Tools LANL (15) (for human immunodeficiency virus), HCV Database Tools LANL (16) (for hepatitis C virus), HFV Database Tools LANL (17) (for haemorrhagic fever virus or Ebola), and hpvPDB (18) (for human papilloma virus). Protein-protein interaction databases such as HPIDB 2.0 (10), PHI-base (12), PID (13), PHIDIAS (19), and PHISTO (20) all provide differing levels of detail, as well as a variety of search tools. More specific databases are available for certain uses, such as HoPaCI-DB (21) for investigations into *Pseudomonas aeruginosa* and *Coxiella*, and the VFDB (22) for virulence factors. Databases such as IntAct (23), BioGRID (24), and Mentha (25) are primarily useful for molecular interactions, and often have more protein-focussed or organism-specific equivalents, such as VirusMentha (7).

Applications

The successful design of drugs and therapeutics to treat infection relies heavily on the knowledge of how the host and pathogen interact. In times where antibiotic resistance is increasing, new strategies are required to treat and prevent infection. There are two main possible strategies for using host-pathogen interactions in drug design: targeting machinery used by the pathogen to disable or reduce its virulence, and targeting machinery used by the host to bolster immune response. Vaccine design typically proceeds *via* the identification of target proteins from the pathogen which can be used as antigens by the immune system. By streamlining the process required to identify new protein targets and immune system mechanisms, drug and vaccine design can be sped up. Therefore, the prediction of key host-pathogen interactions is highly significant to clinical outcomes.

Recent trends in pharmacological design have focussed on both virulence factor disabling and host system boosting (Munguia and Nizet, 2017). The identification of key virulence factors allows for the design of potential inhibitors to neutralize their activity, and possibly render them vulnerable to attack by the immune system, reducing and possibly preventing serious infection. On the other side, therapies can be designed against host mechanisms that are implicated in infection. Strategies such as boosting phagocyte activity as well as reducing immune suppression by pathogens require significant knowledge of how the host and pathogen interact, but present promising leads that allow for the development of non-traditional antibiotics and other therapeutics. Host-pathogen interactions have been used recently in the design of antimalaria drugs *in silico* (Samant *et al.*, 2016), where protein targets were identified through the analysis of protein-protein interaction networks, and the targets subsequently tested for potential inhibitors.

Vaccine design proceeds by targeting the particular features of organisms that interact with the host. This requires knowledge of effector proteins and mechanisms, available through machine learning approaches as well as more traditional structural approaches, followed by experimental validation. Successful prediction of key effector proteins is essential for streamlining the vaccine design process (Zagursky *et al.*, 2003). In the case of viruses, there has been significant progress in recent years towards designing new and more successful vaccines. However, there is still much work to be done, such as in the case of HIV-1 (Haynes *et al.*, 2016). In the case of bacteria, there has also been significant work done in assembling methods to predict protein vaccine candidates (Jaiswal *et al.*, 2013). The study of host-pathogen interactions presents a promising avenue to continue to make progress in this area. Further perspectives can be found in Further Reading 6 (Marston *et al.*, 2014).

Discussion and Future Directions

While much progress has been made in recent years in the investigation of host-pathogen interactions, there are still a number of pressing issues that must be addressed. In broad terms, the main issues can be classed as a lack of detailed understanding of the relationship between pathogens, a lack of variety of different host-pathogen pairs under analysis, and the quality, type, and curation of data available to the community.

There is still uncertainty in how different or similar mechanisms of virulence are across pathogens of related strains, or even related types. As related strains may target different hosts, there can be significant differences between them in terms of how they invade, proliferate, and damage their hosts. However, in the case of *Mycobacteria*, there are distinct similarities between key mechanisms of virulence (Converse and Cox, 2005). More investigation is required into how similar such key pieces of machinery are across strains, species and types, and how possible similarities can be exploited to improve prediction of host-pathogen interactions in newly identified pathogens.

Previous studies from both biological and computational perspectives have focussed on a few key host-pathogen pairs. However, with the variety of infectious diseases already identified, broader and more numerous studies are required to fill in important gaps. Therefore, as the field progresses, it is important that more novel host-pathogen pairs are investigated in the detail that more prominent examples (such as HIV-1, *Mycobacterium tuberculosis*, *Yersinia pestis* and *Plasmodium falciparum*) are.

Computational models are only as good as the data on which they are built. Therefore, it is imperative that the data available for analysing host-pathogen interactions is of the highest possible quality, collected with detailed documentation, labelled and stored in easily accessible ways, and indexed or collated with other data to enable broad analysis across studies and organisms. With a wide variety of different databases available of varying quality which do not contain all current host-pathogen interaction data (as discussed in Section “Databases for Host-Pathogen Interaction” above), there are significant advances to be made in this area. Improvements in text mining methods are a promising avenue for filling in gaps in knowledge; however, they are still lacking in the accuracy required (Thieu *et al.*, 2012). There is also a lack of indexing, maintenance, and reviewing of current host-pathogen

interaction databases, making efforts to find and use already-collected data more laborious than should be required. Therefore, future efforts to curate and review currently available databases, as well as identify areas which are not adequately serviced by current databases, would be extremely valuable.

Closing Remarks

Host-pathogen interactions are vital to our understanding of infectious disease, as well as its treatment and prevention. Through the investigation and analysis of the different stages of infection, the mechanisms by which pathogens invade and proliferate in their hosts can be elucidated. Bioinformatics has and will continue to play a large role in expanding our knowledge in this field, especially in the post-genomic era with the advent of extremely large datasets. Traditional alignment methods, structural analysis, and machine learning methods are all essential to furthering our understanding of host-pathogen interactions, and how such interactions can be exploited to treat disease. The development of novel drugs, vaccines and other therapeutics going into the future will be highly dependent on the knowledge gained from investigating host-pathogen interactions. There is still work to be done in collating and curating data in the field despite significant recent efforts, and this presents an ongoing challenge which must be addressed.

Biographical Sketch

Dean Southwood is a PhD student in the Department of Molecular Sciences at Macquarie University. His background is in theoretical quantum physics, quantum computation, and bioinformatics. His current research interests involve determining novel biomarkers for cancer and disease using machine learning methods.

Shoba Ranganathan holds a Chair in Bioinformatics at Macquarie University since 2004. She has held research and academic positions in India, USA, Singapore and Australia as well as a consultancy in industry. Shoba's research addresses several key areas of bioinformatics to understand biological systems using computational approaches. Her group has achieved both experience and expertise in different aspects of computational biology, ranging from metabolites and small molecules to biochemical networks, pathway analysis and computational systems biology. She has authored as well as edited several books in as well as contributed several articles to Springer's Encyclopedia of Systems Biology. She is currently the Editor-in-Chief of Elsevier's Encyclopedia of Bioinformatics and Computational Biology as well as the Bioinformatics Section Editor for Elsevier's Reference Module in Life Sciences.

Introduction

The research field of bioinformatics is gaining momentum due to its role in the examination of huge volumes of biological data. Nowadays, technological advancements in sequencer and microscope technology have opened many novel and interesting avenues to study organisms at the molecular level. These advances should be accompanied by efficient computational tools and pipelines, geared towards processing and analysis of the data. This combination will allow for more accurate quantification of molecular interaction, and lead to better understanding of the underlying mechanisms. In the field of molecular biology, next-generation sequencing (NGS) technology is playing a key role already. For instance, studies aimed at assessing DNA–protein interactions often make use of chromatin immunoprecipitation-sequencing (ChIP-seq) data, whereas those focused on trying to understand the genetics behind rare diseases or cancers take advantage of whole genome (WGS) or whole exome sequencing (WES) data. Studies that focus on profiling coding and noncoding RNA on a larger scale have the choice of DNA-chip and RNA-sequencing (RNA-seq) technologies. Complex cellular structures can be studied with microscopes that are capable of generating high-quality images. Given the above circumstances, computational algorithms and methodologies are necessary to face such challenges (Roy *et al.*, 2016, 2018; Metzker, 2010). Bioinformatics pipelines combine a set of software tools, each designed to deal with a specific task, to take full advantage of the biological information.

In this article, we discuss the computational pipelines and workflows used for analyzing a wide range of sequencing and biomedical image information. Accordingly, it is hereafter divided into five sections. Section “Genome Analysis” covers genome analysis pipelines, especially tools for dealing with ChIP-seq and genomic variation. Section “Transcriptome Analysis” describes transcriptome strategies, including differential expression analysis, pathway and network approaches, and machine learning (ML) methods for sample subclassification and biomarker discovery. Section “Workflows in Proteomics” focuses on proteomics, specifically on molecular recognition of features in intrinsically disordered proteins (IDPs). Section “Bioimage Analysis Pipelines” briefly introduces the standard workflow for processing bioimages from cellular structures, while Section “Conclusions” highlights the challenges and future directions.

Genome Analysis

The function of molecular structures is ultimately encoded in the genome sequence, thereby bioinformatics pipelines designed for its analysis are of utmost importance. In this section, we present the workflow and tools available for effectively analyzing ChIP-seq and genomic variation data.

ChIP-Seq Pipeline

A great number of studies have been currently focusing on deciphering the molecular consequences of DNA–protein interactions. In this case, NGS data has played a key role because it allows us to sequence the DNA sequence around binding sites. Subsection “ChIP-Seq Pipeline” introduces the standard workflow (Fig. 1) used by many laboratories for such analyses.

Alignment

Because read quality is often affected by artifacts such as adapter contamination and base calling errors, the quality check of reads is sometimes the first procedure before mapping the raw reads to a reference genome. It is here where biases or sequencing errors are identified and low-quality reads are filtered out. Given its flexibility and applicability to many sequencing platforms, the software FastQC (Babraham-Bioinformatics, 2018) is frequently utilized. A more detailed explanation and additional tools can be found in Pabinger *et al.* (2014).

Fig. 1 Standard workflow for the analysis of ChIP-seq data.

After conducting the above filtering, high-quality reads are aligned to the corresponding reference genome using aligners such as Bowtie2 (Langmead and Salzberg, 2012), SOAP (Li *et al.*, 2009b), BWA (Li and Durbin, 2009) and MAQ (Li *et al.*, 2008). It is worth noting that unlike transcriptome analysis pipelines, aligners capable of detecting splice sites are not required whatsoever. The alignment results (the number of uniquely mapped reads) should be carefully checked to validate the success of the mapping procedure.

Quality metrics

When processing ChIP-seq data, the assessment of immunoprecipitation enrichment, sequencing depth or fragment-size selection is a must. This is often referred to as the signal-to-noise ratio and assessed with metrics like strand cross-correlation (Landt *et al.*, 2012) or immunoprecipitation enrichment estimation (Landt *et al.*, 2012). Although the package CHANCE (Diaz *et al.*, 2012) is widely utilized, current peak callers such as MACS (Zhang *et al.*, 2008) already include strand cross-correlation analysis.

Peak calling

Peak calling is one of the most important steps in a ChIP-seq analysis pipeline. It is here where bound DNA regions are detected. Of note, if the improvement of specificity is prioritized, duplicate reads should be removed before peak calling. Moreover, the success of this step will depend on the peak caller and the type of protein being analyzed. For the purpose of analysis, DNA-binding proteins (DBPs) are divided into three groups depending on their binding signals: point-source DBPs, broadly enriched DBPs, and DBPs with mixed characteristics.

Point-source DBPs

These proteins are the most common and therefore many peak callers have been designed to deal with their signals. For instance, peak callers like MACS (Zhang *et al.*, 2008) and SPP (Kharchenko *et al.*, 2008) are able to accurately detect the size of the genomic gap between reads aligned to plus and minus strands. Other software such as BEADS (Cheung *et al.*, 2011) use background models from control samples or GC content for reducing noise. To assess enriched peaks, software such as MACS (Zhang *et al.*, 2008) and CisGenome (Jiang *et al.*, 2010), which rely on statistical distributions, or BayesPeak (Spyrou *et al.*, 2009) and HPeak (Qin *et al.*, 2010), which implement hidden Markov models, are often utilized.

Broadly enriched DBPs

These proteins are usually involved in epigenetic regulation. For their analysis, peak callers such as SICER (Xu *et al.*, 2014) and ZINBA (Rashid *et al.*, 2011) can be utilized to detect broad regions, whereas others such as MACS (Zhang *et al.*, 2008), PeakRanger (Feng *et al.*, 2011), and SPP (Kharchenko *et al.*, 2008) can be used as long as their bandwidth is increased and their peak cut-off decreased.

DBPs with mixed signals

For analyzing molecules with mixed characteristics, for example the RNA Polymerase II, peak callers such as MACS (Zhang *et al.*, 2008), ZINBA (Rashid *et al.*, 2011), and PeakRanger (Feng *et al.*, 2011) can be employed.

Assessment of reproducibility

Because the quality of detected peaks could be affected by the peak caller, sequencing depth, or the number of binding sites, pipelines should always include an assessment of reproducibility. This procedure is intended to check whether the peaks are really reproducible, and should comprise at least two replicates of the same experiment. To do this, it is advisable to filter out those regions with high ChIP signals and then compute the Pearson correlation coefficient of mapped reads at genomic positions. The consistency of peak sets detected in biological replicates is evaluated with the irreproducible discovery rate, and those peaks passing a specific cut-off are finally retrieved. This assessment is often conducted as described in Li *et al.* (2011).

Differential binding analysis

A typical ChIP-seq experiment aims to detect binding differences between biological conditions. Current studies follow two strategies: quantitative and qualitative. The quantitative approach takes into consideration the differential binding between conditions by using the number of reads or the density of reads in peaks. For this, tools such as DBChIP (Liang and Keleş, 2012), which relies on read counts or MANorm (Shao *et al.*, 2012), which uses read densities, can be utilized. The qualitative approach considers overlapping peaks and should only be regarded for exploration purposes. It is important to point out that reproducible peaks should be computed per condition before regarding one of the above strategies.

Downstream analysis

This step comprises important tasks such as peak annotation and motif analysis. The detection of peaks is often not the ultimate goal, but it is followed by the discovery of functional genomic regions. To do this, the peaks should be first formatted in BED or GFF files so that they can be easily analyzed with a genome browser, or annotated with in-house scripts. Current packages such as BEDTools (Quinlan and Hall, 2010) include functions for annotation purposes and calculate the genomic distance of each peak to relevant genomic features. Other libraries like ChIPpeakAnno (Zhu *et al.*, 2010) can be further used for associating binding sites with gene expression activity. On the other hand, motif analysis could also help to identify those genomic sites bound by a specific regulatory protein, thereby facilitating the validation of the ChIP experiment. To detect motif sequences, the genomic regions of the detected peaks are analyzed with motif-discovery software. These algorithms complement each other so that it is advisable to consider different methods. For instance, algorithms such as MEME-ChIP (Machanick and Bailey, 2011) and peak-motifs (Thomas-Chollier *et al.*, 2012) are often employed. Detailed information on motif analysis can be found in Zambelli *et al.* (2013).

Mutation and Genomic Variation

The low cost of NGS technology has made possible international collaborations such as the 1000 Genomes (Genomes Project *et al.*, 2015) and HapMap (International Hapmap Consortium, 2005) Projects. These efforts have provided detailed catalogs of human genetic variation, which are of vital importance to identify disease-associated variants. Consequently, recent studies have aimed at pinpointing genetic risk factors for common diseases, including rheumatoid arthritis and type 2 diabetes, cancers, and Mendelian diseases such as long QT syndrome and Huntington's disease. Because the accurate detection of variants proves critical for clinical treatments and novel drugs, the main challenges are no longer in the sequencing technology but in the development of suitable bioinformatics pipelines. This section addresses two impacted areas: genome-wide association studies (GWAS), and whole genome and exome analysis.

Genome-wide association studies

The genetics behind complex diseases has been long studied by focusing on disease-related genes. However, the massive amounts of genotype data have paved the way for broader approaches like GWAS, which regard linkage disequilibrium at the population level. GWAS has proven absolutely necessary for identifying the genetic risk factors for common diseases (Ozaki *et al.*, 2002; Newton-Cheh *et al.*, 2009), and investigating associations between single nucleotide polymorphisms (SNPs) from case/control studies. The most common tool for GWAS analysis is PLINK (Purcell *et al.*, 2007). PLINK is an open-source and freely available software, which also provides quality controls of the data. It requires two standard formats: PED and MAP files, though binary files such as BED, BIM, and FAM are acceptable as well. The PED file is a space or tab delimited file, composed of a family identifier, individual identifier, father and mother identifiers, gender, phenotype, and genotypes. Of note, when creating a PED file, strand orientation should be checked for allele calls (i.e., forward or reverse complement). The TOP/BOT strand and A/B allele coding, developed by Illumina, along with the database of genetic variation dbSNP (Sherry *et al.*, 2001) are widely used for uniformly designating SNP entries. The MAP file consists of a chromosome, identifier, genetic distance, and physical position for each marker. As for the experimental dataset, it should pass different quality checks in which the samples and markers are carefully examined. The samples should be checked for (1) sex inconsistencies (`-check-sexa`), (2) inbreeding coefficient (`-heta 0.1`), (3) genotype missingness (`-missinga 0.05`), (4) kinship coefficient (`-genomea 0.2`), and (5) population stratification. Similarly, the markers should be checked for (1) genotyping efficiency or call rate (`-genoa 0.99`), (2) minor allele frequency (`-freqa 0.01`), and (3) Hardy-Weinberg equilibrium (`-hwea 0.001`). The remaining dataset can now be used for association analysis (`-assoca`) whose significance cut-off should be set at $p < 5 \times 10^{-8}$. These association results can be further visualized with Q-Q and Manhattan plots included in the R package *qqman*.

Often, the number of markers in an experimental dataset is not enough for accurate analysis, limiting the power and resolution of the GWAS strategy. To overcome this limitation, genotype imputation at ungenotyped loci is strongly recommended. The most common imputation software include IMPUTE2 (Marchini *et al.*, 2007), BEAGLE (Browning and Browning, 2009), and minimac (Neumann *et al.*, 2010). Of note, reference panels from the HapMap (International Hapmap Consortium, 2005) or 1000 Genomes (Genomes Project *et al.*, 2015) Projects should be used.

Thus far, we have described a typical SNP-based association analysis. However, gene-based association approaches can sometimes turn out effective. These statistical methods are classified into three categories: (1) the burden test (Li and Leal, 2008; Madsen and Browning, 2009; Morgenthaler and Thilly, 2007; Price *et al.*, 2010), (2) the variance component test (Wu *et al.*, 2011),

^aPLINK parameter

Fig. 2 Standard workflow for whole genome/exome sequencing data analysis.

and (3) the combination methods (Lee *et al.*, 2012). Recently, a method called SMR, which integrates summary-level data of GWAS and expression quantitative trait locus, was developed (Zhu *et al.*, 2016). Additional examples of risk prediction models for several diseases, which regarded disease-associated genes, can be found in Imamura *et al.* (2013); Shigemizu *et al.* (2014).

Genome and exome analysis pipelines

For rare Mendelian diseases, NGS technology (Metzker, 2010; Rusk and Kiermer, 2008) has made WGS and WES possible at an individual level. Extensive studies have revised the pipelines aimed to detect genetic variations by analyzing NGS data (Hwang *et al.*, 2015; Pabinger *et al.*, 2014). A standard pipeline consists of five main steps: quality check of raw reads, alignment to a reference genome, variant identification, variant annotation, and visualization (Fig. 2). The first two steps are discussed in Section “Alignment” so that we will focus on the remaining steps.

Variant identification

The identification of genomic variants is the main step of a variant detection pipeline. This step is intended to detect genomic variations between biological samples. Most of the available software require the aligned reads in BAM format and sorted by genomic coordinates. Both requirements can be easily achieved with SAMtools (Li *et al.*, 2009a).

The current variant identification tools can be used for detecting (1) germline mutations, (2) somatic mutations, (3) copy number variations (CNVs), and (4) structural variations (SVs). Among the variant callers for discovering germline mutations are the Genome Analysis Tool Kit (GATK) HaplotypeCaller (McKenna *et al.*, 2010), SAMtools (Li *et al.*, 2009a) and VarScan 2 (Koboldt *et al.*, 2012). The GATK includes a statistical model based on Bayesian genotype likelihood for computing genotypes and allele frequencies. Nevertheless, one disadvantage is that it produces many false positives which have to be filtered for downstream analysis (McKenna *et al.*, 2010). SAMtools can be easily integrated into one single pipeline because of its additional functions for aligning reads, as well as sorting and indexing alignment results (Li *et al.*, 2009a). VarScan 2 implements heuristic and statistical approaches for detecting single nucleotide variants, indels, somatic mutations, and copy number alterations between cancer and control samples (Koboldt *et al.*, 2012). SAMtools and VarScan 2, along with SomaticSniper (Larson *et al.*, 2012) can be also employed for identifying somatic mutations. SomaticSniper statistically compares the genotype likelihoods of cancer and control samples, which could turn out useful for cancer-related studies (Larson *et al.*, 2012). Tools such as CNVnator (Abyzov *et al.*, 2011) and ExomeCNV (Sathirapongsasuti *et al.*, 2011) were mainly developed for identifying CNVs. CNVnator combines the mean-shift approach with multiple-bandwidth partitioning and GC correction for detecting atypical CNVs like *de novo* and multiallelic events. However, it often misses CNVs generated by retrotransposable elements (Abyzov *et al.*, 2011). On the other hand, ExomeCNV was specifically created for identifying loss of heterozygosity in addition to CNVs. This software is able to correctly discover small indels due to the inclusion of B-allele frequencies and depth-of-coverage (Sathirapongsasuti *et al.*, 2011). For detecting SVs such as inversions, translocations, or large indels, the software CLEVER is still widely utilized because of its efficient use of internal segment sizes (Marschall *et al.*, 2012).

According to one study that revised several pipelines for whole exome analysis, the combined use of the aligner BWA and SAMtools, or of any aligner with Freebayes, turns out suitable for SNP calling. This study also claims the software GATK (HaplotypeCaller) as the best variant caller for indels, and Freebayes as the most convenient tool when low-quality variants are previously filtered out (Hwang *et al.*, 2015).

Variant annotation

After identifying variants, the detected variants are annotated to understand their biological implications. This step aims to filter out irrelevant variants and retrieve those disease-related ones. Although the current tools are able to annotate SNPs and indels, the annotation of CNVs has not been fully implemented. The available software includes ANNOVAR (Wang *et al.*, 2010), Vcfanno (Pedersen *et al.*, 2016), and VarMatch (Sun and Medvedev, 2017). ANNOVAR can be utilized for annotating SNVs and indels. It analyzes the function of those genes harboring variants, detects variants in conserved genomic stretches, and predicts cytogenetic bands (Wang *et al.*, 2010). Vcfanno includes a “chromosome sweeping” approach, making possible the annotation of a large number of variants (Pedersen *et al.*, 2016). VarMatch can be used when dealing with dense areas of variants or low complexity genomic regions. It implements an optimization strategy known as edit distance, which contributes to improving robustness (Sun and Medvedev, 2017). Furthermore, the detected variants should be matched against those in mutation databases such as dbSNP (Sherry *et al.*, 2001) or COSMIC (Forbes *et al.*, 2008). Consequently, the variants could be classified as deleterious or accepted variants.

Visualization

Variant visualization is also an essential step because it offers better interpretations of the experiment. There are many genome browsers that facilitate the visualization of genomic regions. Some are useful for visualization and annotation, for example, ABrowse (Kong *et al.*, 2012), Apollo (Lee *et al.*, 2013), Ensembl (Ruffier *et al.*, 2017), and GenomeView (Abeel *et al.*, 2012). Others are specifically designed for visualization, including BamView (Carver *et al.*, 2013), JBrowse (Buels *et al.*, 2016), and MapView (Bao *et al.*, 2009). An extensive review of visualization tools can be found in Pabinger *et al.* (2014).

Transcriptome Analysis

Alterations at the genome level, which can be detected using DNA-sequencing approaches such as WGS, are responsible for a wide range of adverse health phenotypes. Such diseases can often be linked to a single mutation within a crucial gene or accumulation of changes that, when combined, can lead to cancer or age-related illnesses (Podolskiy *et al.*, 2016). However, most complex biological mechanisms arise through the interplay of hundreds of interactome elements, with the disease often being a result of perturbation to those systems and networks (Vidal *et al.*, 2011). The most accessible genomic layer, in terms of easiness of profiling and basic examination, is the transcriptome. A global view of gene activity, which takes place at the RNA level, provides means to perform a wide variety of studies. This includes analysis of cellular functions, identification of predictive biomarkers and diseases subtypes, or pathway and network-oriented studies that can more comprehensively explain changes in the state of biological systems (Brodie *et al.*, 2014). Here we will present several computational approaches to study the transcriptome, and avenues to explore when linking such profiles to actionable results. Emphasis will be placed on popular, open-source tools and libraries and on the fundamentals, which can be easily built upon and extended.

Profiling Platforms

The two most widespread platforms for studying global gene changes are NGS and DNA microarrays. The former, a high-throughput approach that superseded Sanger sequencing, relies on “reading” millions of small RNA fragments in parallel. As each RNA transcript is represented by multiple overlapping fragments, it is possible to combine the sequence pieces together by mapping them to a specie-specific reference (Behjati and Tarpey, 2013). DNA microarray (or DNA-chip) technology, on the other hand, uses a collection of DNA probes attached to a solid surface, with each oligonucleotide probe cluster designed to match a specific short region from a gene of interest. Binding a complementary sequence produces a signal (generated by a fluorophore-labeled antibody), whose strength is used to quantify the abundance of the corresponding target gene (Shalon *et al.*, 1996). While the choice between platforms is often based on personal preference and technical capabilities available within a given group, there are several factors that should be considered when making the decision. Microarrays contain a set of predefined target genes, which makes the data processing simple and straightforward. The methodology has matured to a point where the process can be accomplished using a single package – an overview using a representative tool is provided in Section “DNA-Chip Data Processing.” While convenient, the technology does not offer as much flexibility as NGS alternatives (Hurd and Nelson, 2009). If a project would benefit from detecting novel or rare transcripts, fusion genes, or splice variant analysis, or requires higher confidence in the findings (which can be achieved by increasing the sequencing depth of coverage), NGS methods offer an advantage. The analysis of RNA-seq data does, however, require some understanding of the process on the molecular level, as well as familiarity with additional software tools. Each step of the process is described in Section “RNA-Seq Data Processing,” and a graphical overview of the whole transcriptome section is shown in Fig. 3.

DNA-Chip Data Processing

In this section, we will provide a basic overview of initial DNA microarray data processing using limma package (Ritchie *et al.*, 2015) within R software environment. While these steps can be accomplished using manufacturer provided software solutions, limma offers more built-in functionalities and can be easily integrated with other bioinformatics tools. Furthermore, a similar methodology can be utilized for other types of arrays, such as those profiling protein expression levels. R is a statistical computing environment that is widely used for exploratory data analytics and visualization. It can be installed on any operating systems by following the instructions found on the project’s website (see “Relevant Websites” section). Subsequently, a wide range of genomic packages can be downloaded from Bioconductor, a repository for high-throughput genomic analysis tools (see “Relevant Websites” section).

The initial chip processing step is automatically performed by the image analysis software, where the TIFF scan of the array is translated into a list of intensities for each of the small “spots” (i.e., areas with multiple copies of a unique DNA probe). limma provides a read function that loads and converts data (together with sample annotation) from a wide range of microarray formats. Probe annotation, usually stored in GenePix Array List (GAL) format, should be provided separately, in case it is not included in the output files.

Issues with the sample quality can be introduced at any stage of preparation, from low-quality biological material to problems during scanning. It is thus important to detect such problems early during analysis. There are two common quality control

Fig. 3 Graphical overview of the standard pipeline for transcriptome data analysis.

strategies that are applicable to both individual spots within arrays (much higher complexity) and to cross-array comparison – assigning quality weights that are used in a downstream analysis or removing problematic cases (Kauffmann and Huber, 2010). limma has built-in functions to cover the former, which calculate spot weight quality as well as array variance (Ritchie *et al.*, 2006). Lower scores are assigned to spots with quality issues and to arrays that are less reproducible, ensuring that results are not affected by bad samples. Alternatively, arrayQualityMetrics package (Kauffmann, 2009) can be used to calculate and visualize the distance between arrays and exclude those that are significantly different from the rest.

When measuring the fluorescence intensities there are several factors that affect the scan, by introducing ambient noise, both within and between the arrays (Silver *et al.*, 2009). Such signals are adjusted with background correction algorithms, which estimate and remove nonspecific binding or spatial heterogeneity effects (Ritchie *et al.*, 2007). Plotting the foreground against the background intensities can guide the choice of optimal correction algorithm. Lastly, the samples should be normalized to ensure that the biological signal is not “diluted” by technical variation or biases. Depending on the type (single- or two-color) and technology of the array, limma provides several approaches to normalize (i.e., remove some of the variations) within and between the arrays. This ensures that all samples are on the same measuring scale and that technical differences are not influencing the results. The choice of algorithms for background correction and normalization is the only challenging step in the processing of DNA microarrays, and both should be guided by the assessment of the data. As the subsequent steps in the analysis are common between sequencing and DNA-chip platforms, they will be described together in Section “Differentially Expressed Genes and Visualization.”

RNA-Sequencing Data Processing

The field of NGS profiling encompasses a wide range of protocols, though from the analysis standpoint the main difference lies in the type of sequence that is enriched during library preparation. These can include small regulatory RNA such as miRNA, total or coding RNA, degraded RNA (German *et al.*, 2008), or RNA amplified from a single cell rather than a population of cells (Eberwine *et al.*, 2014). While there are differences in how each of the types is analyzed, the initial data processing steps and general principles are similar. The section below will focus on processing data from total or polyA selected RNAs, though with small changes to the reference the methodology can be applied to other types of protocols. For the purpose of this section, we will presume that the sequencing was performed on Illumina’s HiSeq or MiSeq machine, and that demultiplexing (the process of separating individual libraries that were sequenced on the same lane) was performed during data export to FASTQ files. FASTX-Toolkit (Hannon, 2010) and EMBOS seqret (Cock *et al.*, 2010) are two useful tools for checking, manipulating, and converting FASTQs to match the input format requirements of other programs.

The quality of reads, or short sequences obtained at the end of NGS protocols, depends on the integrity of the initial sample, proficiency in library construction, and handling during final sequencing stage. FastQC (Babraham-Bioinformatics, 2018) is a quality control tool that generates comprehensive graphical reports on several important characteristics of any sequence data. It should be noted that modern alignment algorithms can deal with cases such as adapter (short DNA sequences used in library preparation and sequencing) contamination or when part of the reads are of lower quality. However, in more severe cases,

trimming the sequences or removing the adapters can increase the quality and number of aligned reads. This can be achieved using tools such as Cutadapt (Martin, 2012), FASTX (Hannon, 2010) or Trimmomatic (Bolger *et al.*, 2014). It is important to repeat the quality control step after each manipulation to ensure that the overall quality of the library has improved. If the entire length of the reads is of very low quality (below the score of 20 for Illumina's version 1.3 or later encoding), adapters make up most of the reads, or there is a significant overexpression of few "background" genes (such as ribosomal RNAs), it is usually advisable to repeat the sample and/or library preparation. The aims of the project and type of data will naturally influence the software stack and parameters used in the data processing. Differential splicing and metatranscriptomics assembly require a more complex setup, though the principles are the same once the fundamentals are understood. For the purpose of this and the next three subsections, we will focus on transcriptome profile comparison between two phenotypes or conditions.

The RNA-Seq reads are small sections of the transcriptome, hence the traditional way of processing them was to align the reads to a reference genome or transcriptome. From there, the reads were "stitched" together, and the overlap with regions of interest was used for abundance estimation. Abundance can be calculated for exons, transcripts, or genes, though gene-level analysis is generally recommended when transcript information is not required. Transcript quantification is more challenging due to a combination of short sequencing length and lack of unique sequences in many splice variants. Increasing the read length through gradual improvements in the technology will solve this problem in the near future. A prime example of the "traditional" approach is STAR aligner (Dobin *et al.*, 2013), where the genome index created prior to mapping is used during alignment. STAR gained widespread adaptation due to high-performance relative to other methods available at its launch. After the alignment is completed, programs such as featureCounts (Liao *et al.*, 2014) are run to count the mapped reads to genomic features, and provide a summary of the alignment. The postalignment report contains information on the percentage of mapped, unique, and duplicated reads, and serves as a final quality check before downstream analysis. A more detailed overview of the alignment can be generated using RNA-SeQC (DeLuca *et al.*, 2012). A recently developed alternative to this software stack is the so-called "pseudoaligners," which instead of aligning to the reference, determine read compatibility with defined targets (Bray *et al.*, 2016). kallisto is an example of such approach, and the algorithm has not only been shown to be very fast but also accurate and more robust to errors (Bray *et al.*, 2016). The transcript level abundance estimates produced by kallisto can be converted to counts using the R package tximport (Soneson *et al.*, 2015), after which they can be analyzed in the same fashion as any other alignment result. Lastly, and similarly to DNA-chip data, the reads should be normalized so that a comparison can be made between samples from different lanes or sequencing runs. Fragments per kilobase of transcript per million mapped reads (FPKM) is a popular expression unit that normalizes for sequencing depth and corresponding gene length. A similar type of normalization can be achieved in tximport using the lengthScaledTPM parameter, which is the final step in the processing of raw sequencing reads.

Differentially Expressed Genes and Visualization

The downstream analysis of normalized counts varies greatly depending on the experimental design, type of data and sample characteristics. While biological replicates and appropriate controls are crucial in many studies, in settings such as clinical bioinformatics, the lack of controls or a low number of samples is still common. Whenever paired samples are available (e.g., control and treated, or normal and diseased tissue from the same patient), differential expression analysis is usually performed first. It is a quantitative measure of expression change that can be used to rank genes based on a degree of under- or overexpression. It is a good practice to remove lowly expressed genes beforehand, which can be accomplished either using sophisticated software models or more simply by removing genes with a count ≤ 10 .

Fold change, or the magnitude of change between conditions, is a preferred method for quantification of differential expression. It can be calculated using a variety of packages such as limma, DESeq2 (Love *et al.*, 2014), or sleuth (Pimentel *et al.*, 2017), all of which offer technically advanced though slightly different implementations. For a simpler manual calculation, the genes should first be transformed to account for the presence of extreme values and mean-variance dependency. This is most commonly achieved using log2 transformation, though alternatives such as rlog or VST are also used (Lin *et al.*, 2008). Subsequently, the log2(mean) of all replicates from a healthy control/untreated samples are subtracted from the log2(mean) of all replicates from a disease phenotype/treated samples. For datasets with no paired samples, a comparison can be made between groups with and without a certain condition or phenotype.

Visualization is an important component in bioinformatics as it is challenging to identify patterns in tens of thousands of genes based on text data alone. The most common graphics libraries used for high-quality plotting are ggplot2 in R (Ginestet, 2011) and matplotlib in Python 3 (Hunter, 2007). The built-in statistics and graphics capabilities in R are usually sufficient for initial data exploration purposes. Bioinformatics investigation is often initiated with a thorough check on how closely the samples match the experimental design. This is performed to identify population structures in the data that are previously unknown, or subgroups of samples with different characteristics. Furthermore, outliers, or samples with abnormally low or high values (which could represent technical issues), can be identified and removed. Principal component analysis (PCA) helps to find such characteristics by obtaining a combination of variables, in this case, gene expression values, that best differentiate the samples (Abraham and Inouye, 2014; Sharma and Paliwal, 2007). Any aberrant samples should be removed at this stage so that they do not influence the results. Subsequently, two-group expression comparison can be visualized using MA plots, which show the relationship between logged fold change and mean expression. Such plots are equally suited for diagnosing data-related issues as well as checking the number, magnitude, and pattern of differentially expressed genes. Another way of exploring global changes in gene expression is

the Kolmogorov-Smirnov nonparametric test. It compares the distribution of each gene between two defined groups and is a good approach to visualize changes in mean expression and variability. The above-mentioned plots show general patterns of expression and should be supplemented with more direct visualizations. A very popular and information-rich example is heatmaps, which are two-dimensional grids where a range of values is represented by colors. They are often paired with hierarchical clustering, which sorts rows (which represent gene expression) and columns (which represent samples) in a way that most clearly shows patterns in the data. The combination can reveal commonly regulated genes or sets of samples with distinct expression profiles and characteristics (such as disease subtypes). Another way of using heatmaps is correlation matrices, which show a correlation of expression between multiple genes. More advanced plotting methods often contain a higher density of information within a single figure, utilizing colors, shapes, and opacity in a third-dimensional space.

Functional, Pathway, and Network Analysis

While global profiling of gene (or protein) expression provides a significant amount of information, it is often challenging to link such results to tangible biological insights. Employing annotation regarding a gene's (or its product's) involvement in a certain biological process, signaling pathway, or molecular function is one of the most effective approaches to study RNA-Seq data. Gene set enrichment analysis is one of the most widely used solutions, which verifies if the differentially expressed gene results show an enrichment or depletion of genes associated with a certain biological aspect (Subramanian *et al.*, 2005). This can include genes connected with cancer development, drug response, a wide range of signaling pathways, and more (Curtis *et al.*, 2005). There are numerous approaches for performing gene set analysis (e.g., overrepresentation analysis, pathway topology), most of which are implemented in R or are available as online tools (Tarca *et al.*, 2013). Pathway information can be easily retrieved from online databases such as KEGG (Kanehisa *et al.*, 2016), Reactome (Fabregat *et al.*, 2016), or WikiPathways (Slenter *et al.*, 2018), either manually or using the associated application programming interfaces. A different approach makes use of topological properties of genes within molecular interaction networks. Based on the direct interaction partners, or close proximity neighbors, it is possible to infer novel insights such as biological function (Sharan *et al.*, 2007) or prioritize candidate disease genes (Yu *et al.*, 2013). Cytoscape is the most popular environment for network studies (Shannon *et al.*, 2003), though it is also possible to perform a wide variety of network analyses using igraph in R (Csardi and Nepusz, 2006) or networkx in Python 3 (Hagberg *et al.*, 2008). Weighted gene coexpression network analysis is a great example of a network-based exploratory tool that provides additional data reduction and feature selection capabilities (Langfelder and Horvath, 2008). It is based on correlation patterns between gene expression, which forms the basis for finding clusters of potentially associated genes. It also identifies relationships between multiple such modules. Network approaches are also very useful for integrating different types of data, such as multiomics profiles (e.g., mutation, expression, or methylation datasets) or electronic medical records. Similarity network fusion is a popular example – it constructs a network of samples for each data layer and fuses them into a combined structure (Wang *et al.*, 2014). This approach strengthens strong signals (i.e., similarities between layers) and allows the samples to be grouped into distinctive subtypes.

Machine Learning Approaches in Genomics

The unprecedented growth in volume and complexity of biomedical datasets and literature has made bioinformatics analyses more challenging than ever. The very high ratio of features (e.g., mutation or expression) to the number of samples, and the considerable time investment needed to achieve expert-level knowledge on a particular biological phenomenon translate into the additional level of complexity. This has led to growing popularity of ML approaches, algorithms designed to automatically learn from data without an explicit set of rules to follow. While genomic datasets pose many unique challenges that need to be considered, ML algorithms can be extremely useful, particularly when combined with standard bioinformatics tools and databases. There are three main types of algorithms that are of direct use to genomic studies – unsupervised, supervised, and semisupervised. They are all easily accessible through Python, R, or Java libraries, although it requires familiarity with statistical analysis and programming.

Unsupervised learning is geared towards inferring “hidden structures” in unlabeled data – labels being the output values that in biological context can mean disease subtypes, months of patient survival or type of response to a treatment. Given the previously mentioned high number of features, dimensionality reduction is the first area of interest. PCA has traditionally been used to reduce the dimensionality of the data by geometrically projecting them onto lower dimensions (Lever *et al.*, 2017). This transformation allows for noise removal and easier classification, though recently developed t-distributed stochastic neighbor embedding was shown to outperform it in some biological applications (Fonville *et al.*, 2013). Such methods can be combined with pathway annotation to better explain variations in the phenotype (Ma and Kosorok, 2009). One of the primary aims of personalized medicine efforts is finding subgroups of patients with distinct phenotypes, which would allow for a more tailored prognosis, care, and treatment. To this end, a plethora of clustering approaches are routinely used on genomic data, mainly in hopes of finding novel disease subtypes (Van Rooden *et al.*, 2010). Hierarchical clustering, k-means, and spectral clustering are popular algorithms, though many specialized methods have been created specifically for biomedical application (Sharma *et al.*, 2017a,b,c, 2016a).

When label data is available, supervised learning approaches can be used to identify significant features or build models to predict categorical classes (classification) or continuous values (regression). While the identification of biomarkers for

detecting and monitoring diseases has long been a focus in medicine, in many cases more complex models are needed to make an accurate diagnosis (Kidd *et al.*, 2015). Overfitting is a common challenge when building prediction models – given the high number of features in genomic datasets, it is relatively easy to find a combination of genes that will correlate with outcome labels by pure chance. Such results will not generalize well when tested with an independent dataset. It is thus important to separate the data into training and testing datasets (a popular split is 70%–30%), and only use the latter for sporadic validation of the model. Models with fewer features and lower complexity are always preferred, especially if the features are already known to be predictive of the outcome of interest, or are connected to a biologically relevant mechanism or pathway. The baseline prediction performance can be established using simple annotation (patient information, sample characteristics) or using biomarkers already reported in the literature. Such model can be further expanded or replaced entirely depending on its performance and complexity. Subsequently, feature selection approaches (Sharma *et al.*, 2012a,b,c,d, 2014, 2011; Sharma and Paliwal, 2011) can be applied to find biological components that best explain the phenotype of interest. Simple univariate methods such as t-test or Pearson’s correlation were shown to be the optimal methods for feature selection in genomic data (Haury *et al.*, 2011). Alternatively, tree-based algorithms or recursive feature elimination paired with an estimator are popular choices as they allow to rank features based on their importance to the model. Once a subset of features is selected, a model can be constructed using a variety of algorithms – LASSO, ElasticNet, and random forest regressor are popular choices for predicting quantity while support vector machine (SVM), random forest classifier, or k-nearest neighbors (kNN) are popular for predicting categories. More advanced strategies such as boosting, bagging, or stacking can be used to decrease variance or increase accuracy – xgboost, being a representative example, usually provides satisfactory out-of-the-box (i.e., using default parameters) results (Chen and Guestrin, 2016). Neural networks, while popular in many fields such as medical image recognition, are used more sporadically in biomedical applications where decision-making transparency is often crucial. An iterative process of constructing, tuning (i.e., tweaking parameters), and testing the model is usually performed on the training data, using a 10-fold cross-validation (CV) technique. The process partitions the data into 10 equal parts and uses nine parts for training and one for evaluation. This is repeated 10 times, each time using different parts of the data for training and testing, and the final result is calculated as an average from all the runs. The performance metric depends on the type of the label, with accuracy, precision, and recall being popular for classification and root mean squared error and coefficient of determination (R^2) for regression. Once satisfactory results are achieved, the model should be trained on the entire training data (70% in our example) and tested on the remaining test data (the leftover 30%). The performance of a good model should show comparable or better results relative to the 10-fold CV evaluation. While some improvements can be achieved using different ML algorithms or by tweaking the parameters, poor performance usually means that the selected features are not enough to predict the outcome. Feature engineering, or creation of novel features using domain knowledge, is often the best approach to improve the model (Ang *et al.*, 2016). A more recent development in the ML field is semisupervised algorithms, which take advantage of the information contained within unlabeled data in classification problems (Scholkopf and Zien, 2006). Mixing unlabeled and labeled data has been shown to improve the supervised learning accuracy and is of particular interest to biology, where unlabeled data is abundant but labeled data is difficult to obtain.

Workflows in Proteomics

Proteomics is an extensive field of research where a plethora of studies are being conducted. These studies cover the following areas: protein fold recognition, structural class prediction, function analysis, posttranslational modification, and molecular recognition of features (Dehzangi *et al.*, 2018, 2017; López *et al.*, 2018, 2017; Chou, 2017). Various bioinformatics tools and packages have thus been developed for advancing the above research areas. The implementation of modern pipeline frameworks requires detailed guidelines and often offers a command line or workbench interface. In this section, we survey on the pipeline frameworks for identifying molecular recognition features (MoRFs) in IDPs. Specifically, we emphasize the design strategy of MoRF prediction systems and provide practical recommendations based on the requirements of high-throughput bioinformatics analyses.

The Necessity of Molecular Recognition Feature Prediction

In the traditional view of protein structure–function paradigm, proteins fold into a stable three-dimensional structure that ultimately determines their function. However, recent progress in computational and experimental methods has revealed a lack of this stable tertiary structure in certain protein regions (Dyson and Wright, 2005, 2015; Lee *et al.*, 2014; Uversky, 2014). Proteins comprising such regions are called IDPs and reportedly have important biological functions related to signal transduction and cell regulation (Wright and Dyson, 2015; Lee *et al.*, 2014). IDPs often achieve their functions through the loosely structured MoRF region. This region binds to a structured partner and consequently undergoes a disorder-to-order transition to adopt a well-defined conformation (Lee *et al.*, 2014). MoRF length varies up to 70 amino acids. Although there are many documented experimental techniques for identification and analysis of MoRF regions, they are still expensive and time-consuming. To overcome this

challenge, computational approaches have become absolutely necessary for predicting these MoRFs in disordered protein sequences (Sharma *et al.*, 2018a,b, 2016b; Malhis *et al.*, 2016; Disfani *et al.*, 2012; Dosztányi *et al.*, 2009).

State-of-the-Art Molecular Recognition Feature Predictors

An abundance of computational methods and predictors have been already developed to predict MoRFs. These include ANCHOR (Dosztányi *et al.*, 2009), MoRFPred (Disfani *et al.*, 2012), MoRFchibi (Malhis and Gsponer, 2015), MoRFPred-plus (Sharma *et al.*, 2018a), MoRFchibi-web (Malhis *et al.*, 2016), PROMIS, and OPAL (Sharma *et al.*, 2018b). OPAL, the latest proposed predictor, has also proven the most accurate predictor in the literature. The above-mentioned predictors are currently available as online web servers and downloadable software packages. The subsequent sections illustrate the guidelines of MoRFs prediction and how to evaluate the pipeline of MoRF prediction.

Fundamentals of Protein Sequence Analysis

Sequence

The protein sequence is retrieved from an experimental setup where all the amino acids of the protein or peptide are determined. For computational analyses, a large number of protein sequences are at present available in different databanks, which were generated and annotated through high-throughput technologies.

Feature source and feature extraction technique

The features of protein sequences can be captured from different sources of information. These can be chemical, physical and physicochemical properties of amino acids, evolutionary and structural information of protein sequences, functional domains, and gene ontology information of protein sequences.

Some of the existing feature extraction techniques have been used to create feature vectors from protein attributes such as occurrence, composition, transition and distribution, pairwise frequencies, amino acid composition, autocorrelation, and bigram (Sharma *et al.*, 2013, 2015; Liu *et al.*, 2015; Dehzangi *et al.*, 2015; Du *et al.*, 2014). Early studies used to focus on sequential, syntactical, and physicochemical features. However, more recent studies have considered evolutionary-based features because they tend to provide good prediction accuracy for protein-related problems (Sharma *et al.*, 2018a; Yang *et al.*, 2017; Lyons *et al.*, 2016; Dehzangi *et al.*, 2015).

Classifiers

For classification purposes, several classifiers have been widely explored, including SVMs, artificial neural networks, kNN, as well as ensembles of classifiers. Amongst the aforementioned classifiers, SVMs is a well-known classifier that has delivered promising results in recent studies (Sharma *et al.*, 2018b; Malhis and Gsponer, 2015).

Design of a Molecular Recognition Feature Predictor

This section will cover the benchmark dataset and the framework of MoRF prediction.

Benchmark dataset

A wide collection of benchmark databases has been introduced, assembled, and used for developing MoRF predictors. These repositories include MoRFPred, MoRFchibi, MoRFPred-plus, MoRFchibi-web, and OPAL (Table 1).

The sequences in TRAIN and TEST464 sets were obtained from Protein Data Bank and filtered to retain protein-peptide regions of 5 to 25 residues in size (Disfani *et al.*, 2012). The sequences in TEST464 share a less than 30% sequence identity with sequences in TRAIN (Disfani *et al.*, 2012). MoRF predictors are always trained using the sequences in TRAIN set and assessed using the sequences of TEST464 set (Sharma *et al.*, 2018a,b; Malhis and Gsponer, 2015; Malhis *et al.*, 2016). According to the principles used to assemble TRAIN and TEST464 sequences, it is not verified whether identified protein-peptides are disordered in isolation and also TEST464 is not free of redundancy as its sequences share more than 30% sequence identity to each other (Disfani *et al.*, 2012). In order to address the above and validate a MoRF predictor, the EXP53 set is often used. The EXP53 set contains 53 nonredundant protein sequences with MoRFs which have been experimentally verified to be disordered in isolation (Malhis *et al.*, 2016; Sharma *et al.*, 2018b).

Table 1 Description of OPAL benchmark dataset

Datasets	No. of sequences	Total residues	No. of molecular recognition features (MoRF) residues	No. of non-MoRF residues
Training set	TRAIN	421	245,984	5396
Test sets	TEST464	464	296,362	5779
	EXP53	53	25,186	2432
				240,588
				290,583
				22,754

Fig. 4 Framework of molecular recognition feature (MoRF) prediction.

Framework of Molecular Recognition Feature Prediction

Fig. 4 shows the framework of MoRF prediction, whose input is the protein sequence. For prediction purposes, protein sequences are commonly represented using different features. These characteristics comprise physicochemical properties of amino acids such as 544 common physicochemical indexes (Kawashima *et al.*, 2008), evolutionary profiles such as position specific scoring matrix generated with PSI-BLAST (Altschul *et al.*, 1997) and hidden Markov model profiles generated with HHblits (Remmert *et al.*, 2011), as well as structural attributes such as secondary structure, accessible surface area and dihedral torsion angles predicted by tools as SPIDER2 (Yang *et al.*, 2017). To predict each residue in the protein as MoRF and non-MoRF, a sample is first extracted, described as a feature vector, and finally predicted with a suitable classifier.

Fig. 5(A) outlines the bioinformatics tools/scripts and the data format required for implementing a framework of MoRF prediction. These tools are generally run on a Linux operating system and protein sequences are organized in a FASTA format file. Tools such as PSI-BLAST, HHblits, and SPIDER2 can be installed and run via command line. On the other hand, scripts are written with software tools such as MATLAB, OCTAVE, and C-code. Finally, **Fig. 5(B)** shows the procedure of training and scoring a MoRF predictor.

Implementation Steps of a Molecular Recognition Feature Predictor

To identify MoRFs in a protein sequence, each residue should be initially scored. This score will help predict the residues as MoRF or non-MoRF. Two of the methods often used in a MoRF classification scheme are ResidueMoRF and RegionMoRF. These methods are used to extract samples from protein sequences during the training and test steps. The following subsections will discuss the training and test steps, which are of utmost importance to construct a MoRF predictor.

Training step

In this step, features are extracted from MoRFs and non-MoRFs and grouped in a training set. Let us assume the segment F , which represents a MoRF with flanks, and the segment G , which describes a non-MoRF with flanks. Both segments F and G are from a protein sequence in the training set. Let us also suppose that a protein sequence P_i is given as

$$P_i = A_1 A_2 \dots A_j \dots A_{n_i} \quad (i = 1, 2, \dots, T) \quad (1)$$

where A_j is the j th amino acid in the sequence, T is the total number of protein sequences in the training set, and n_i is the length of the protein sequence P_i . For instance, let us consider a protein sequence P_1 whose length $n_1 = 150$ and which contains one MoRF located between A_{30} and A_{40} . The segments F and G for this protein P_1 are illustrated in **Fig. 6**. For illustration purposes, a flank size of 20 amino acids has been considered. Of note, the flank size should be selected during training and evaluation.

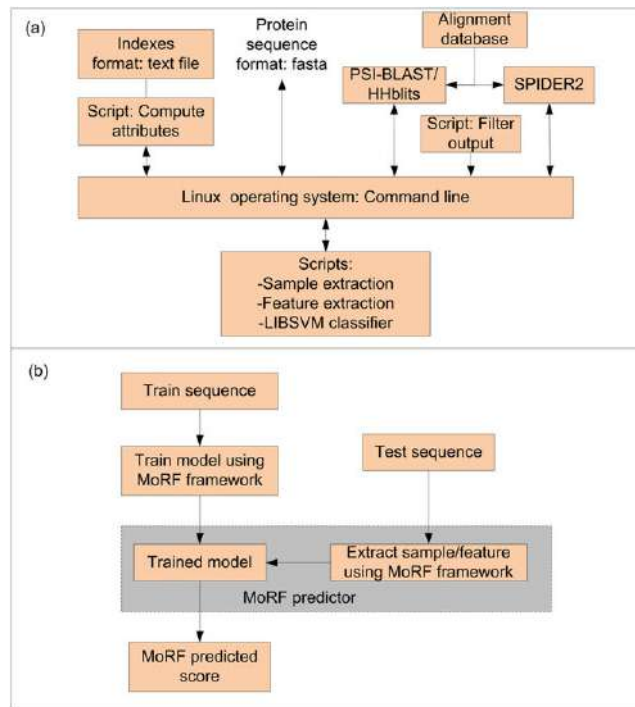

Fig. 5 Pipeline of molecular recognition feature (MoRF) predictor implementation. (A) details of bioinformatics tools/scripts and data formats, (B) procedure of training and testing a MoRF predictor.

Fig. 6 Schematic illustration of (a) segment F and (b) segment G.

MoRFs can have a variable length of 5 to 25 amino acids. Additionally, zeros are padded to create flanks of 20 amino acids if the MoRF is present at the beginning or end of the protein sequence. Positive and negative samples representing MoRFs and non-MoRFs are extracted from segments F and G, respectively.

For sample extraction, two methods named ResidueMoRF and RegionMoRF, which are detailed below, are commonly used.

ResidueMoRF method

With this method, a window size of 41 ((flank size $\times$ 2) + 1) amino acids is regarded for extracting samples from a segment. For extracting positive samples, the center of the window is placed on the MoRF residue of segment F, with amino acids upstream and downstream of the MoRF residue. For example, the sample S_x for a MoRF residue is defined as

$$S_x = \{A_{x-20}, \dots, A_{x-2}, A_{x-1}, A_x, A_{x+1}, A_{x+2}, \dots, A_{x+20}\} \quad (2)$$

where A_x is the MoRF residue (i.e., in Fig. 7(A), $x=30$). Positive samples extracted from a segment F using Eq. (2) are interpreted as

Fig. 7 Graphical illustration of (a) sample extraction from segment F , (b) sample extraction for scoring a query protein sequence of length L (A_j is the j th amino acid in the sequence), and (c) sample extraction from a query sequence of length L .

$$\gamma_{tr} = \begin{cases} S_x \\ S_{x+1} \\ \vdots \\ S_{x+l-1} \end{cases} \text{ for } 5 \leq l \leq 25 \quad (3)$$

where l is the MoRF length (i.e., in Fig. 7(A), $l=11$). Fig. 7(A) shows the graphical illustration of sample extraction from the segment F . In a similar way, negative samples are extracted from segment G .

After applying either of the above models, the feature vector is finally computed from the sample and used for model training.

RegionMoRF method

With this method, the entire segment F with a MoRF region of length l (as depicted in Fig. 7(A)) is taken as a positive sample. Likewise, the entire segment G is taken as a negative sample.

Test step

The scoring of each residue in a query protein sequence also requires the extraction of samples. In this case, the sample extraction procedure makes use of the above methods ResidueMoRF and RegionMoRF as well.

ResidueMoRF method

Like the procedure described in the above section, a window size of 41 ((flank size $\times 2$) + 1) amino acids is used to extract a sample for each query residue. The sample S_j represents a query residue defined as

$$S_j = \{A_{j-20}, \dots, A_{j-2}, A_{j-1}, A_j, A_{j+1}, A_{j+2}, \dots, A_{j+20}\} \quad (4)$$

where A_j is the residue in the query sequence and $j=1,2,\dots,L$. Samples extracted using Eq. (4) for a query sequence of length L are described as

$$\gamma_{ts} = \begin{cases} S_1 \\ S_2 \\ \vdots \\ \vdots \\ \vdots \\ S_L \end{cases} \quad (5)$$

Fig. 7(B) shows the graphical illustration of sample extraction from a query sequence. Like the procedure followed for training, zeros are padded to make the length of flanks equal to 20 if query residues are at the beginning or end of the sequence. The feature vector is then computed from the sample and used for scoring.

RegionMoRF method

With this method, a window of size $(2 \times \text{flank size} + l)$ is used to extract samples from a query sequence. The sample S_j for a query sequence is defined as

$$S_j = \{A_{j-20}, \dots, A_{j-2}, A_{j-1}, A_j, A_{j+1}, A_{j+2}, \dots, A_{j+(l-1)+20}\} \quad (6)$$

where A_j is the residue in the query sequence and $j=1,2,\dots,L-l+1$. Samples extracted using Eq. (6) for a query sequence of length L are interpreted as

$$\gamma_{ts} = \begin{cases} S_1 \\ S_2 \\ \vdots \\ \vdots \\ S_{L-l+1} \end{cases} \quad (7)$$

where $l=6,7,\dots,30$. A graphical illustration of sample extraction can be observed in Fig. 7(C). Eq. (8) defines the samples used for scoring each of the residues as

$$A_i \rightarrow \begin{cases} \{S_1, S_2, \dots, S_i\}, 1 \leq i < l \\ \{S_{i-l+1}, S_{i-l+2}, \dots, S_i\}, l \leq i \leq L-l+1 \\ \{S_{i-l+1}, S_{i-l+2}, \dots, S_{L-l+1}\}, i > L-l+1 \end{cases} \quad (8)$$

where $i=1,2,\dots,L$. By varying l from 6 to 30, 450 $(6+7+\dots+29+30)$ samples are obtained for each residue, except for the residues at the beginning and end of the query sequence. The feature vector is computed from the sample and used for scoring. For each residue, the maximum score of the samples defined in Eq. (8) is set as final propensity score.

Summary of Molecular Recognition Feature Prediction

For the prediction of MoRFs in protein sequences, state-of-the-art predictors such as ANCHOR, MoRFPred, MoRchibi, MoRFchibi-web, and OPAL are currently available as web servers. Thus, end users or scientists can easily use a graphical web interface to predict MoRF and non-MoRF residues in a protein sequence. Except for MoRFPred, the other predictors can be further installed and configured locally (in personal computers). The performance of the above-mentioned predictors is shown in Table 2. As it clearly shows, the OPAL predictor outperforms the other approaches, achieving a significant accuracy and confirming its practical use in real scenarios.

To select a target protein for further experimental analysis, the sequences of large databases need to be scored. To do this, the end user can write SQL query scripts to obtain such scores from the MoRF predictor (Fig. 8(A)).

As Table 2 clearly indicates, the prediction accuracies are still limited when it comes to selecting a target protein for further experimental analysis for drug design. However, these limitations can be further improved by considering certain strategies. There is a need for high-performance workbenches, which could be accessible via the web to obtain protein sequence alignments. In the current MoRF web servers, the alignment tools are locally installed and run instead of using available alignment web servers. This is partly because alignment tools require a huge amount of time to provide alignment results. In addition, future MoRF pipelines similar to the one in Fig. 8(B) are expected. In other words, a core database server should store the experimental annotation from research labs whereas the computational annotation should be guaranteed by high-throughput bioinformatics analyses.

Table 2 Performance of state-of-the-art MoRF predictors. The results are reported for the TEST464 and EXP53 datasets using the area under the curve (AUC) as the performance metric

Predictor/method	TEST464	EXP53
ANCHOR	0.605	0.615
MoRFPred	0.675	0.620
MoRFchibi	0.743	0.712
PROMIS	0.790	0.818
MoRFchibi-web	0.805	0.797
OPAL	0.816	0.836

Bioimage Analysis Pipelines

One of the areas in bioinformatics which is experiencing an enormous transformation is related to bioimage analysis. This is because a great number of bioinformatics applications are relying on image data for assessing different cellular and molecular mechanisms and thus validating the biological hypothesis. More and more images of biological mechanisms are generated by microscopes every single day, making necessary the design of accurate computational approaches.

In this direction, distinct imaging techniques such as PALM (Betzig *et al.*, 2006), STORM (Rust *et al.*, 2006), and STED (Hell, 2003) are currently able to detect individual proteins separated a few nanometers. Moreover, images related to biological mechanisms like RNA interference and chemical compounds (Echeverri and Perrimon, 2006; Moffat *et al.*, 2006; Sepp *et al.*, 2008) are absolutely necessary to shed light on scientific problems such as the differentiation of cancer cell phenotypes (Long *et al.*, 2007a).

However, the complexity of bioimages makes it extremely difficult to apply conventional medical image analysis workflows because the objects of interest sometimes possess different morphologies and intensities. Therefore, it is necessary to start paying attention to this emerging subfield of bioinformatics, which is not widely covered in the scientific literature.

The development of bioimage analysis pipelines often consists of the following steps (Fig. 9): preprocessing in which noise is reduced, image registration (Qu *et al.*, 2015) where images are aligned for pixel-by-pixel comparisons, image segmentation (Meijering, 2012) in which the objects of interest are separated from the background, feature extraction where object descriptors such as shape (Pincus and Theriot, 2007) and texture (Depeursinge *et al.*, 2014) are computed, classification where objects are detected by ML techniques (Shamir *et al.*, 2010), and visualization (Walter *et al.*, 2010).

Fig. 9 Bioimage analysis workflow.

In this section, we will go through each of the above steps and explain the different methods.

Preprocessing

Preprocessing should be the first step of any pipeline. Its main objective is to improve the appearance of a bioimage or highlight additional information about the objects of interest, which might not be clearly observable. Many enhancement techniques and filters are often used to enhance the contrast and borders of the different objects, accentuate space frequencies, and remove or attenuate noise. One of these contrast enhancement techniques is histogram adjust, which produces a histogram with a specific form for the output image. Histogram equalization achieves good approximations towards a uniform distribution of the values of gray scale levels, giving the same occurrence probability to all gray levels (Pratt, 2014). To overcome the limitations of standard histogram equalization, the contrast-limited adaptive histogram equalization (CLAHE) technique is sometimes used. It divides the images into contextual regions and applies the histogram equalization to each of them (Pratt, 2014). This evens out the distribution of used gray values, making the hidden features of the image more visible. Another technique is the wavelet transform, which increases the image contrast and facilitates well-localized decomposition schemes (Salvado and Roque, 2005). In addition, digital filters are also used for enhancing bioimages by reducing noise and preserving the borders of those objects of interest. Some of these filters are Prewitt and Canny operators, as well as median, Gaussian, and average filters.

Image Registration

This step is often included in pipelines intended to compare images of different biological conditions such as those for building brain atlas (Ng *et al.*, 2007), and for comparing cell morphology and gene expression patterns. Here, methods such as mutual information registration (Viola and Wells, 1997), spline-based elastic registration (Rohr *et al.*, 2003), and congealing registration (Learned-Miller, 2006) can be utilized. Image registration has been used for blastoderm embryos in *D. Melanogaster* where each nucleus is described using a point in the 3D space (Fowlkes *et al.*, 2008).

Image Segmentation

The main aim of the segmentation step is to separate the objects of interest from the background. It is sometimes considered as a classification process of the objects present in the image because it can easily locate the different objects. Segmentation methods can vary depending on the specific application and image type. However, a segmentation method able to reach acceptable results for all types of bioimages has not been developed thus far. For a better explanation, we will present the segmentation methods in two groups: classical segmentation and clustering methods.

Classical segmentation methods

Thresholding is a method that segments scalar images, creating a binary partition of the image intensities. Once thresholding determines an intensity value, segmentation is achieved by grouping all the pixels based on intensity into two different classes. Its main limitation is that it only considers the intensity instead of other relationships between the pixels. One of the most reported methods is the Otsu's method, which selects the optimal threshold by maximizing the between-class variance with an exhaustive search. Although there are different methods to find a threshold, most of them are not satisfactory when analyzing real images, such as bioimages, due to the presence of noise, plain histograms, or an inadequate illumination.

Another classical method is deformable models, which are based on physical motivations, and used to delineate the borders of regions using curves or closed parametric surfaces deformed under the influence of external and internal forces. Two important deformable models are snakes (Kass *et al.*, 1988) which segments objects whose morphology is variable, and intelligent scissors (Liang *et al.*, 2006) which allows us to segment with minimal user interaction.

Clustering methods

Clustering techniques are also important in biomedical analysis pipelines because they achieve a correct separation of the regions of interest from the image background. Two of the frequently used clustering techniques are fuzzy C-means (Dulyakam and Rangsanseri, 2001; Yang *et al.*, 2004) and hierarchical clustering, including single-linkage, complete-linkage, and average-linkage.

The segmentation of bioimages depends on which features are needed. For instance, texture features can be extracted for chromatin compositions whereas concavity features could be employed for nuclear morphology. When the images are of cell-based assays where nuclear compartments are colored, methods such as globular template segmentation, watershed segmentation, or active contour/snake methods are recommended.

Nevertheless, when the images contain nonglobular objects such as neurons, the neuroanatomical analysis software NeuroLucida (Glaser and Glaser, 1990) is often used. Alternatively, directional kernels are also considered for searching neuronal structures in confocal images (Al-Kofahi *et al.*, 2003). Finally, the tool ImageJ plugin NeuronJ (Meijering *et al.*, 2004) is advisable as well.

Feature extraction/selection

The feature extraction/selection step is of vital importance when we aim to classify objects in bioimages. In this step, representative feature vectors are usually obtained. To do this, dimensionality reduction techniques like PCA are necessary. In addition, in-depth knowledge of the research domain is needed because it will allow us to select those features that can help discriminate between objects of interest. For example, if the aim is to analyze dynamic fluorescent images, texture features should be used (Dorn *et al.*, 2008). For clustering gene expression patterns, global decomposition by eigen-embryo analysis is recommended (Peng *et al.*, 2006) whereas wavelet features able to detect global and local properties are advisable to recognize and annotate gene expression patterns (Zhou and Peng, 2007). When a collection of image characteristics is extracted, we would then recommend the use of minimum-redundant maximum-relevant feature selection algorithms (Ding and Peng, 2005; Peng *et al.*, 2005b) so that redundant features can be eliminated.

Classification

The classification step is also of vital importance in bioimage analysis pipelines because it is here where the features of the object of interest will be used for classification. Standard ML techniques are often employed to achieve this goal. Some of these classifiers are the following:

- Bayesian classifiers, which rely on the Bayes' theorem, can be used in binary classification problems. The naïve Bayes classifier is often employed for classifying objects of interest because it requires a small amount of training data for parameter estimation.
- The kNN rule (Kuncheva, 2014) does not require knowledge of a priori probabilities whereas it assigns an unknown object to the class of its nearest neighbor in the measurement space. Moreover, it does not require patterns to be represented in a suitable vector space but only a similarity measure or distance function.
- Decision trees (Kuncheva, 2014) do not use comparison functions to infer general properties of the training matrix. Nor do they use all the features for object classification but each class can be inferred using its own feature set.
- SVMs (Hastie *et al.*, 2001b) search the hyperplane that separates a set of training objects while maximizing the margin between their classes. This method aims to minimize the bound on the generalization error rather than minimize the mean squared error over the dataset.

When the training set consists of few bioimages, an ensemble of machines is advisable. This strategy builds several basic classifiers and combines their outputs for improving classification. In such cases, a diverse ensemble in which the classifiers have adequately different decision boundaries is needed. To achieve this diversity, strategies such as bagging, boosting, AdaBoost, stacked generalization, and a mixture of experts are often considered (Kuncheva, 2014; Polikar, 2006). Bagging (Kuncheva, 2014; Polikar, 2006) draws different training subsets with replacement and is particularly recommended when the number of images is limited. Boosting (Kuncheva, 2014; Polikar, 2006) makes new machines pay more attention to those examples in which previous machines produced errors. AdaBoost (Kuncheva, 2014; Polikar, 2006) generates a set of hypotheses by training weak machines and making sure that the cases misclassified by previous classifiers are included in the training data of the next classifier.

One of the methods used for clustering mRNA expression patterns of coexpressed genes was the minimum spanning tree cut (Peng *et al.*, 2006) whereas for determining cell identities, the absolute three-dimensional location of the cell along with its location patterns was employed (Long *et al.*, 2008). However, for assigning bioimage patterns to different annotation terms, parallel classifiers are highly recommended (Zhou and Peng, 2007).

Visualization

As in other bioinformatics pipelines, visualization is vital for result verification. Among the techniques often used in bioimage analyses are surface and flow visualization. Tools for the visualization of images of protein surfaces and gene expression can be utilized in addition to immersive visualization systems such as NCMIR's ATLAS and ImmersaDeskTM (Ai *et al.*, 2005).

Conclusions

The spectrum of bioinformatics tools and methods is currently too wide for an exhaustive review. The computational approaches grow in sophistication alongside technological improvements in the corresponding experimental protocols. New requirements, which become more evident with increase in volume and complexity of biological data, will further push the development of

efficient and comprehensive solutions. This article covers four main research areas: genomics, transcriptomics, proteomics, and bioimage analysis.

Within the genomics area, we presented current efforts that focus on accurate mapping of sequences to the reference and identifying regions that show variation. As the number of quantifiable changes will continue to rise, new frameworks geared towards integrating this information and linking them to phenotypic changes will be required.

In the transcriptome section, we examined several computational data processing approaches and covered linking expression profiles to actionable results. We summarized popular tools and libraries that can be easily built upon and extended. As our understanding of pathways, networks and omics interaction grows, so will the scope of the analyses. Future solutions will look at RNA changes more in the context of global interaction network, rather than few genes with higher or lower expression.

For proteomics, we have provided a detailed guideline for MoRF prediction, including data description, examples of state-of-the-art tools, MoRF classification schemes, and pipelines of MoRF downstream analysis. Any reader can easily follow the steps to develop a new MoRF predictor, and thus analyze MoRFs in protein sequences using the presented methodology.

Finally, within the bioimage analysis area, we described the standard workflow for analyzing digital images, which includes preprocessing, image registration and segmentation, feature extraction, classification, and visualization. With the capture of high-resolution images of different cellular mechanisms, future bioinformatics approaches will definitely be necessary to keep up with the technological advances.

Author Contributions

AS and PJK defined the structure of the article. YL, AS and PJK wrote the abstract, introduction, and conclusions. YL and DS covered Section “Genome Analysis” (Genome). PJK covered Section “Transcriptome Analysis” (Transcriptome). RS and AS covered Section “Workflows in Proteomics” (Proteome). YL covered Section “Bioimage Analysis Pipelines” (Bioimages). AS and TT oversaw and managed article creation.

Introduction

The processing and analysis of data, such as from next-generation sequencing experiments requires multiple steps, many of which have complex sets of requirements. Running these steps in an ad-hoc manner can be very repetitive, time consuming and prone to human error. These shortcomings can be overcome through the utilization of computational pipeline tools, designed to streamline multiple complex analysis steps by linking the individual components into a single robust, efficient and reproducible workflow.

Dedicated pipelines remove the repetitiveness of the analysis and a single command can run a multiple-step pipeline on thousands of samples, whilst at the same time eliminating human error in the manual specification of the parameters required by the pipeline. As the pipeline runs the expectation is that a log file is generated with the version of the tools used, specified parameters, genome version, warning and error messages. These logs record the provenance of the analysis permitting the exact same analysis to be performed by researchers without access to the same hardware or pipeline tool.

In this article, we outline the features of several pipeline frameworks in terms of their job running efficiency and reproducibility. However, the choice of pipeline tools should also take into account the accompanying information provided by the pipeline tool project, for example, user documentation and resources provided by the user community. The development of pipeline frameworks and the defining of individual pipelines have many of the same requirements as the bioinformatics tools the pipelines call. For example, good documentation including manuals, quick start guides and code commenting make implementing the pipelines more manageable (Karimzadeh and Hoffman, 2017). Consideration should also be made to the reproducibility of the software, support for standard file formats, log file and version tracking (List *et al.*, 2017). The future adoption and support of the pipeline tool/framework will depend on its ease of use and ability for the users to write their own new pipelines.

Four key requirements we consider to be essential for a computational pipeline tool are:

1. Log provenance of analysis (e.g., version, parameters, genome release).
2. Standardized analysis across experiments.
3. Customizable, user created pipelines.
4. Utilize job scheduling where available.

Other important pipeline tool features include job dependencies where jobs await the execution of the steps upstream in the pipeline producing the required input. Non-dependent jobs can be run in parallel. In combination with a job scheduler this allows the individual steps in a pipeline to run as efficiently as possible. Check-pointing is also a very desirable feature, where pipelines can be restarted from the failure point rather than having to execute the entire pipeline from the start (Leipzig, 2016).

The primary take home message from this article is that to achieve robust and reproducible bioinformatics analyses it is vital to make use of a dedicated pipeline tool. Furthermore, the most appropriate tool should be selected based on the available computer infrastructure, user experience and project size.

Definitions of Hardware Levels, Project Sizes and User Experience Levels

One of the first considerations for choosing a pipeline framework to implement is the hardware available to run the pipelines (Fig. 1). This may be at the modest level of a single laptop for small scale project or prototyping right up to large, many thousand central processing unit (CPU) high performance computing (HPC) clusters. Cloud based solutions can scale beyond typical HPC installations if resources are available. Here we define four levels of hardware to aid selecting the most appropriate framework for the hardware available.

- Level 1: Laptop. Multicore (2+), RAM (8 GB+).
- Level 2: Node. Multi-processor (1–2), Multicore (4+), RAM (64 GB+).
- Level 3: HPC. Multi-processor, Multi-nodes (2+, typically 100 s), RAM (64 GB+).
- Level 4: Cloud. Multi-processor, Multi-node (2+) RAM (64 Gb+).

A further consideration is the project size which could range from a small RNA-Seq experiment consisting of six samples (e.g., 3 control and 3 case), up to a large-scale cohort study including many thousands of samples. Unless there are dedicated systems administrators available to install and maintain a pipeline environment the ease of install and usage are important factors in the choice of pipeline framework. User experience can range from a bench biologist wanting to analyze their data in a robust and reproducible manner up to seasoned bioinformaticians running pipelines on a production level scale for example at the EBI working towards the Ensembl releases on a three-month cycle.

Fig. 1 Decision flowchart for choosing a suitable pipeline tool. There are many routes through the decision chart as each project or situation will have unique and changing requirements. We have highlighted five routes we consider to lead to the most appropriate choice for some typical environments. The red route is the least optimal as no dedicated pipeline framework is utilized.

Pipeline Tools

In this section, we will discuss a selection of popular pipeline tools and highlight their strengths and weaknesses. We will also introduce more generally applicable resources such as virtualisation and cloud based frameworks which are particularly well suited to developing bioinformatics pipelines.

Each pipeline tool uses its own terminology for the elements comprising a fully functional workflow or pipeline. To simplify the terminology, we define some common terms and concepts.

- Module/process: an independent, self-contained task in a pipeline, for example, the adapter and quality trimming of fastq files.
- Pipeline/workflow: constructed by linking together modules/processes to achieve an objective. [Fig. 3](#) depicts a simple RNA-seq data processing pipeline.
- Pipeline tool/framework: an implementation of multiple pipelines or workflows with necessary supporting libraries. A pipeline framework can also include other features such as viewing and creating figures from the analyses.
- Job scheduler: software to control and manage unattended background execution of jobs. A job scheduler will queue jobs until the requested resources (processor and memory) are available. Examples of job scheduling software are Simple Linux Utility for Resource Management (SLURM), Grid Engine (SGE), Portable Batch System (PBS) and Load Sharing Facility (LSF).
- Serial/parallel job processing: a job can run as serial processes, where each instruction is performed in turn; or in parallel where instructions are performed at the same time on different or multi-node processors.

Ad-Hoc/Shell Scripts

At the simplest level, a collection of tools can be combined into a pipeline using shell scripts, a set of commands to be run by the Linux Shell (e.g., BASH). These are often simple to create and require customisation for each project. There are many advanced features that can be incorporated into shell scripts. However, scripts lack the two main features of an efficient data processing pipeline: the ability to launch jobs on the completion of dependent jobs and check-pointing ([Leipzig, 2016](#)). With this in mind, and the difficulty in writing and maintaining scripts can be avoided by using dedicated workflow/pipeline tools.

ClusterFlow

ClusterFlow was developed as an easy to use and install pipelining system for bioinformatics applications ([Ewels et al., 2016](#)), and can be run on any level of hardware, with and without a dedicated job scheduling system. Internally, ClusterFlow uses pre-defined modules to build pipelines which are run as shell scripts tailored to the system hardware. For example, on a laptop the pipeline would run in serial for a set number of CPU cores. On a full cluster the bash script would launch the pipeline steps in parallel with queuing controlled by the job scheduling system. There are currently over 40 modules defined in ClusterFlow, using over 25 bioinformatics tools and there are over thirty predefined pipelines, an example of a simple RNA-Seq workflow is shown in [Fig. 3](#). Writing custom modules involves the tool command and options to be defined in a Perl module, requiring a moderate knowledge

of coding. Once created, modules can be included in pipelines defined as a nested list of tools to be run. The indentation and nesting defines the order the tools must be run and their dependencies. For example, a trimming step must complete before an alignment is started. As a pipeline completes a log file is generated capturing any log output from the tools in the pipeline as well as version information for the tools run. This is harvested at run time so produces the actual tool and genome version used. An email notification system runs when the job has completed, or of any issues that occurred during the run. ClusterFlow is unable to re-queue failed jobs, but does report the errors in log files.

Nextflow

NextFlow is a domain independent pipeline tool with strong support for bioinformatics applications (Di Tommaso *et al.*, 2017) with tasks such as operations on common bioinformatics file formats are included as part of the core distribution. Pre-made bioinformatics pipelines are available from the Nextflow user community and are curated on the NextFlow website. The installation and initial set-up are non-trivial and require an experienced bioinformatician with systems administration skills. However, once set up NextFlow provides a very robust system for running pipelines with check-pointing allowing pipelines to be restarted from any point if failures are encountered. Modules can be written in any language (e.g., Perl, Python, Bash) and can use existing scripts, this has an advantage of not requiring new modules to be specifically written for Nextflow. Modules are then incorporated into pipelines in the NextFlow 'dataflow programming model' build as an operating system and hardware independent Java Virtual Machine. Nextflow is also compatible with Docker, permitting pipelines to be scaled up to a full HPC system or to cloud instances.

Bpipe

Bpipe (Sadedin *et al.*, 2012) is a Java/Groovy based pipeline tool for bioinformatics, designed to take existing command line tools and shell scripts and wrap them into robust pipelines. The syntax has been selected to ease the transition from existing shell script based pipelines into Bpipe. Each task of the pipeline is written as a separate module allowing new pipelines to easily be built from existing tasks. Check-pointing is implemented so jobs can be restarted from a failure, in addition to the generation of log files as the pipelines proceeds. Non-interdependent tasks can be run in parallel and are compatible with job scheduling tools to fully optimise running jobs on different scale hardware. The tasks and pipelines are hardware independent so can be easily shared across different architectures.

Snakemake

Snakemake (Köster and Rahmann, 2012) is a scalable pipeline system based on the Python language with in-built check-pointing. The specification of the number of cores/threads on the hardware and the job scheduling system enables snakemake to scale from single core platforms to large multi-node clusters. For each snakemake run a directed acyclic graph (DAG) is generated with nodes representing the specified jobs to be run. A useful feature is the ability to export the DAG as an image for the pipeline to allow visualisation of the structure of the pipeline (Similar to Fig. 3). In this way, non-dependent jobs can be run in parallel, and with further configuration of the multi-threaded nature of some programs CPU usage can be optimised. The check-pointing system permits pipelines to be restarted, and with an output file check, pipelines can be re-started from the last successfully completed step rather than having to restart the entire pipeline. If a step of the pipeline fails then snakemake performs an automatic cleanup of output files from these incomplete jobs. Users can create and distribute snakemake workflows via code repositories such as GitHub, however to date no central repository for user-contributed pipelines exists.

eHive

eHive (Severin *et al.*, 2010) is a Perl workflow management system, utilising job schedulers such as LSF to submit jobs to the compute clusters. Large compute clusters work on the concept of a centralised job queue and a job controller. Bottlenecks arise in the job controller as cluster nodes need explicit instructions for each and every job execution. A few seconds latency between job submission and execution can translate into a significant overhead when the scheduling system needs to handle millions of jobs. The core concept of *eHive* is that jobs are not scheduled by central controller, instead are modelled on a honeybee queen in a hive with her worker bees. The queen will create workers using a job creation/selection algorithm by observing the central blackboard. It is designed with the aim of moving job scheduling away from a centralised controller yet retaining the ability to monitor jobs as they progress. Eventually a system emerges with very small (3 ms) job overhead, fault tolerance and optimised utilization of computing clusters with more than 1000 cores.

The main console for *eHive*, the *beekeeper*, creates *workers* as required and submits them to the compute cluster, reporting their progress. In this model, workers need not be aware of the existence of other workers, rather only the steps prior and downstream of itself in the pipeline. Each worker generates and stores partial solutions to problems communicated indirectly through the central blackboard. Workers are autonomous and have the ability to create additional jobs, analyses, dataflow and control rules as they run. A MySQL database is used as the central blackboard detailing the jobs and processes to be run in the pipeline. In a centralised pipeline tool, a job will retrieve input data from a shared resource and in some cases store results into a common database. This

Fig. 2 Architecture of *eHive* Pipeline Tool. (A) Different components of *eHive*, the Blackboard (MySQL database) containing job list and the data flow rules; *beekeeper*, console that create workers and submit jobs to compute clusters; Workers, which run in the LSF job scheduling system. (B) A typical *eHive* Analysis module. Three key stages in a typical *eHive* analysis module lifecycle.

has the potential to create bottlenecks if there are a large number of jobs running at once. In *eHive*, the database can anticipate significant numbers of concurrent write requests via the implementation of an InnoDB database engine to enable row-level-locking supporting concurrent table updates. Jobs can also be processed in batches to mitigate this issue. Once a worker is created, it will register its choice of analysis on the central blackboard and load the modules needed to execute the analysis. Subsequent workers will grab and execute jobs available from the central blackboard. As the jobs progress, workers log their process status on the blackboard, finally setting the job status to done once completed without errors (Fig. 2).

Through these optimisations *eHive* can easily handle tens of millions of jobs and has been successfully tested with SGE, PBS and the default LSF job scheduler. *eHive* has been used in several large scale international bioinformatics projects as a key infrastructure of the data coordination centre, for example, the Ensembl (Aken *et al.*, 2017) and Ensembl Genomes Project (Kersey *et al.*, 2016), the Functional Annotation of Animal Genomes project (FAANG) (Andersson *et al.*, 2015) and the International Genome Sample Resource (ISGR) (Clarke *et al.*, 2017), as well various other high throughput genomics and epigenomics projects. To illustrate *eHive*'s industry scale capacity; the *eHive* InterProScan pipeline (Jones *et al.*, 2014) is run every three months in Ensembl and Ensembl Genomes, where protein domain annotations are run for over 1000 genomes, against 11 million protein sequences. *eHive* chunks the sequences into smaller sets and runs the InterProScan protein domain identification. The resulting XML files of identified signatures are then parsed and stored in the respective genome databases. The pipeline usually runs for 7–10 days, requiring regular monitoring via *guiHive* (Cunningham *et al.*, 2015) or a MySQL interface to ensure the beekeeper is still alive, and creating beekeeper jobs are typically due to memory limits or missing files, but can be easily restarted with the check-pointing system.

Virtualization

Rather than run pipelines directly on the available hardware via a dedicated pipelining system such as those outlined above, virtualisation provides a layer of abstraction with benefits such as being agnostic to the local hardware and operating system (OS). In essence, virtualisation is the ability to run multiple virtual computers on a single computer (e.g., laptop). Containers are stripped down virtual machines just containing the required parts of the operating system to run the required programs. The main advantage of virtualisation is the portability and the popularity of tools such as Docker in the wider computing community have created a large user base with extensive online resources.

Docker

Docker containers are a method of packaging together the minimal required elements required to run a piece of software or pipeline such as the source code, runtime environment, system tools, and system libraries. This makes an efficient, lightweight,

self-contained systems ensuring software will always run reproducibly, regardless of where it is deployed. Containers and Virtual Machines have a shared heritage so are similar as in having resource isolation and allocation benefits, however architectural differences have given containers the advantage of being both portable and efficient. Virtual Machines typically comprise the main application, binaries and libraries as well as the entire guest OS and can be tens of GBs, running independently of the host OS. Contrary to this, containers have the same capability of a Virtual Machine, excluding the full OS in favour of sharing a kernel with other containers, running as isolated processes in user space on the host operating system. A further advantage of containers is their ability to isolate applications from one another as well as the underlying hardware, providing an additional layer of protection for the application a.k.a secure by default.

Docker is utilized across many disciplines, not just bioinformatics, however there are several projects providing domain specific resources for bioinformatics pipelines. These range from tutorials and documentation to repositories of community created pipelines and containers for bioinformatics software (see Relevant Websites Section). Bio-Docklets ([Kim et al., 2017](#)) are an effort to ease the creation of bioinformatics pipelines using Docker. Each tool in the pipeline is containerised in an individual *docklet*, with wrapper scripts combining the docklets into a pipeline.

Pipeline Cloud Environments

In a next generation sequencing project with a high number of samples and/or read depth is likely to require the availability of high performance computing hardware. If this is not available, or a rapid scale-up is required, then cloud based environments are an attractive alternative to local hardware. However, it is worth stating that as with all cloud based storage, the data may be located in a different country potentially violating the policies of data storage for many government organisations and charities. A key advantage of many of the available pipeline cloud environments is a graphical interface to run and create pipelines, rather than relying on command-line execution or coding.

Galaxy

Galaxy ([Afgan et al., 2016](#)) is targeted at researchers who do not want to design and run pipelines via the command line as pipelines can be designed graphically via the Galaxy interface accessed via an Internet browser. There is a large user community providing implementations of individual bioinformatics tools as well as complete pipelines. The Galaxy team also present regular user and developer meetings ensuring a thriving community supporting the platform. Galaxy can be accessed via public servers, local installs or via cloud instances.

Seven Bridges and DNANexus

There are several commercial cloud-based bioinformatics environments, with Seven Bridges (see Relevant Websites Section) and DNANexus (see Relevant Websites Section) being the most widely known. Both provide a large range of pipelines for the most common types of NGS analysis. However, a completely novel/custom pipeline would require working closely with the commercial teams. An open source alternative, Arvados (see Relevant Websites Section) can be installed and run on private cloud instances, or via a commercial partner Curoverse (see Relevant Websites Section). The main advantage of cloud solutions is the ability to instantly scale up analysis without having to worry about the underlying hardware, the cost of cloud deployments is usually on a cost-effective pay-per-usage model. The commercial solutions also allow users to interact via web-based graphical interfaces or the command line for more advanced users.

Pipeline Languages

Each of the pipeline tools introduced in this article require the pipelines to be defined and coded in a tool specific manner. While some effort has gone into making pipelines portable, e.g., the ability to import shell scripts into NextFlow, it is a very attractive prospect to define pipelines in a truly environment agnostic manner. To address this the common workflow language was, and continues to be developed.

Common Workflow Language

The Common Workflow Language (CWL) aims to standardise the language used to define pipelines and allow the sharing of pipelines across the different pipeline systems ([Amstutz et al., 2016](#)). The vision is for a researcher with a pipeline developed in for example Clusterflow to be able to share the code with a researcher using Arvados without needing to re-implement the pipeline from scratch. This inherent portability from using CWL is also advantageous if a pipeline on local hardware requires a rapid scale up to run on a cloud environment for a specific project. CWL is supported in NextFlow, Galaxy, Seven Bridges, DNANexus and Arvados.

Worked Example

To highlight the differences of the implementations of workflow in a selection of pipeline tools we provide a worked example for a simple RNA-Seq pipeline as a bash script (Fig. 3), in *ClusterFlow* and in *eHive*. We provide example code and documentation for each pipeline tool on Github (see Relevant Websites Section). In our simple paired-end RNA-Seq example there are six main steps, with requirements for jobs to complete before the next can proceed (i.e., dependencies). The initial quality control is performed with FastQC and trim_galore. The alignment with HiSat2 is dependent on trim_galore completing. Post-alignment gene quantification using htseq-counts and quality assessment using Qualimap require the alignment step to complete. Finally, once all jobs in the pipeline are complete for a sample then a summary report is generated with MultiQC. In the bash script example, each step in the pipeline is executed sequentially as the job dependencies are not defined. Each step can run as multithreaded jobs, but the overall efficiency of the pipeline is far from optimal. In the *ClusterFlow* and *eHive* examples the jobs are executed in a dependency aware manner, allowing efficient deployment of the pipeline jobs across samples. *eHive*'s check-pointing system will automatically restart failed jobs, and with the further optimisations detailed above is particularly suited to very large scale projects.

With the recent development and rapid adoption of single cell RNA sequencing (scRNA-Seq) it is worth highlighting the differences to the worked example above in terms of the creation of a reproducible and robust pipeline. There are several scRNA-Seq tool suites available, for example: Seurat, Scater and Monocle (Zappia *et al.*, 2017), however these could benefit from tighter integration with high performance computing environments and the robustness of pipeline tools for reproducible analysis. As the number of single cells in a typical experiment can easily be over 100,000 depending on the sequencing protocol, particular attention must be given to the quality control steps including filtering, normalisation, and drop-out modelling so are a critical component of any single cell pipeline (Svensson *et al.*, 2017).

Discussion

When it comes to pipeline design, there are various tools available and considerations to be taken into account. Here we illustrate a selection of tools and outline some key metrics (Table 1), which we feel that can aid in the process of decision making. Depending on the importance of a certain metric(s) to the project, one could then decide on the most appropriate tool to use. For instance, due to a short delivery time-frame for a small size project, a tool that is easy to install, new modules and pipeline can be easily built are of paramount importance. With this in mind, one could then look at *ClusterFlow* as potential tool solution as it satisfies the requirements for logging and the use of a job scheduler. At the other end of the spectrum, when analysis reproducibility, tool robustness and re-queuing capabilities are essential, *eHive* or *Galaxy* are strong candidates. It is absolutely critical from the outset to have a clear understanding of the project characteristics, available resources and output delivery in order to make the optimal decision on the pipeline tool to use. The use of pipeline frameworks in designing computational pipelines will ease the management of multiple pipelines, reducing the need for manual intervention, therefore minimizing errors and increasing the robustness and reproducibility of

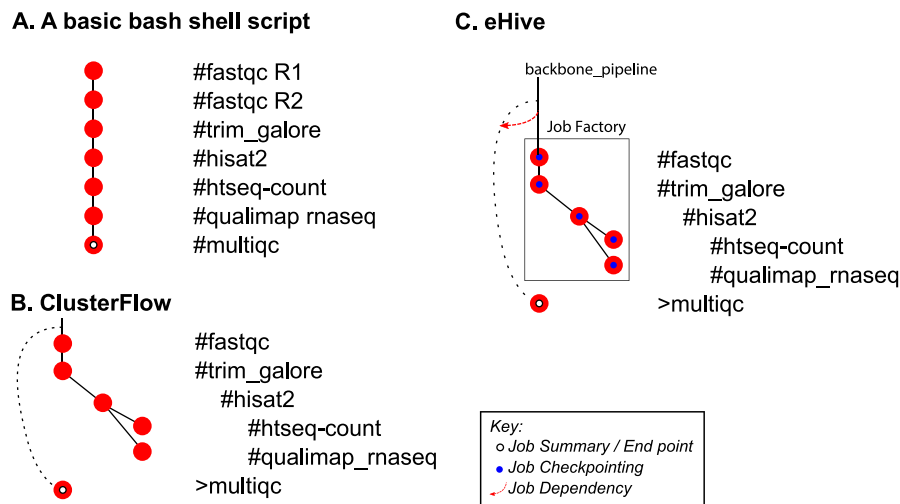

Fig. 3 A schematic highlighting the different job architectures for three pipeline tools. (A) Simple bash shell script with each of the pipeline steps executed in series requiring each job to be completed before launching the next. (B) *ClusterFlow* implements job dependencies, where jobs wait for their dependent job to be completed before launching. Non-dependent jobs can launch and run in parallel. A final step can be specified, in this case a MultiQC report, to run once all other jobs have completed. (C) *eHive* also has job dependencies, but with additional error checking and checkpointing. In this way pipeline jobs can be restarted from the last completed step. In all cases multithreading can be implemented in the specification of the tools being run, allowing within job parallelisation. Example code for each of the pipelines (A,B,C) can be freely accessed. Available at: <https://github.com/darogan/ConstructingComputationalPipelines/>.

Table 1 Comparison table for pipeline tool features

<i>Metric</i>	<i>BASH</i>	<i>ClusterFlow</i>	<i>NextFlow</i>	<i>eHIVE</i>	<i>Galaxy</i>
Ease of install	Easy	Easy	Moderate	Advanced	Moderate
Pre-made modules	No	Yes	Yes	Yes	Yes
Ease of writing modules	Easy	Moderate	Moderate	Advanced	Easy
Ease of writing pipelines	Easy	Easy	Moderate	Advanced	Easy
Use of queueing system	Partial	Yes	Yes	Yes	Yes
Checkpoints/re-queueing	No	No	Yes	Yes	Yes
Tool version logging	No	Yes	Yes	Yes	Yes
Pre-defined genome locations	No	Yes	Yes	Yes	Yes
Hardware level compatibility	1,2,3	1,2,3	1,2,3	2,3	2,3,4
Cloud compatibility	No	No	Yes	Yes	Yes
Inbuilt Docker support	No	No	Yes	No	Yes
Large scale projects	No	No	Yes	yes	Yes
Common Workflow language compatible	No	No	No	No	Yes
Under active development	N/A	Yes	Yes	Yes	Yes

Five options for running pipelines are compared for features supported by the tool as default. In many cases the feature compatibility is possible with customisation and an advanced level of expertise. Hardware levels are defined in the Introduction (1. Laptop, 2. Node, 3. HPC, 4. Cloud).

the analyses. The RNA-Seq worked example illustrated here is a basic implementation to demonstrate how a pipeline is constructed within three different frameworks. For examples of more comprehensive analysis pipelines, we recommend the GATK best practices for variant calling on whole genome and exome high-throughput sequencing projects (Auweru *et al.*, 2013). The variant calling pipeline includes many quality control steps such as marking duplicates, base quality recalibrations and filtering for variants. GATK also produce their own workflow data language (WDL) for constructing pipelines.

Future Directions

One of the key issues that must be addressed to ensure the widespread adoption of robust pipeline frameworks is the lack of interoperability of defined pipelines (e.g., RNA-Seq) between the different pipeline frameworks. Currently, it is not trivial to share a defined pipeline between frameworks, however with the standardization of languages for defining pipelines (e.g., CWL or WDL) and platform independent frameworks for running software (e.g., Biocontainers) there is a clear route to achieve this in the near future (Leprevost *et al.*, 2017).

Closing Remarks

The primary aim of this article has been to guide users into selecting the most suitable pipeline tool for their project and available resources. With all the advantages of automating robust bioinformatics pipelines it should be stated that this should not be at the expense of understanding the underlying processing and analyses being performed. Bioinformatics should never be thought of as a black-box, and careful thought must be applied to ensuring the most appropriate tools are being used.

Biographical Sketch

ChuangKee is a proven research and informatics leader in the life science and pharma drug discovery space with hands on computational and informatics experience. In his role as Data Coordinator/Manager at OpenTargets (collaboration between EBI, GSK, Sanger Institute & Biogen), He manages data providers across various different groups, and drives data integration efforts. ChuangKee joined OpenTargets from Ensembl, one of the most successful large scale bioinformatics projects in history. Most recently he was the Senior Technical Officer in the Ensembl's production team, responsible for large scale processing pipelines, production infrastructure development, data coordination among sub-teams to ensure delivery of releases consisting of thousands genomes. Before Ensembl, ChuangKee was the Principal Scientist, VP at Sime Darby Technology Centre (SDTC). He headed the bioinformatics, data analysis department whose efforts were geared toward enhancing palm oil yield using high throughput assays such as NGS. Prior to joining SDTC, ChuangKee was a Senior Associate Scientist at Eli Lilly. He lead various cross-functional, -discipline drug discovery informatics projects to support target identification and validation in various therapeutic areas. Before Eli Lilly he was with Medical Research Council in Edinburgh. ChuangKee has a Masters in Bioinformatics from Chalmers University of Technology in Sweden.

Russell Hamilton heads the bioinformatics core facility at the Centre for Trophoblast Research (CTR), University of Cambridge. The focus of the CTR is the study of the placenta and maternal-fetal interactions during pregnancy and brings together over 25 Principal Investigators based in different departments within the University of Cambridge and Babraham Institute. He has previously worked in industry at Cambridge Epigenetix (CEGX) developing epigenetics tools to enable single base resolution sequencing of methyl-cytosine (mC) and hydroxymethyl-cytosine (hmC). Prior to this was a senior postdoc in the Department of Biochemistry at University of Oxford, working on the RNA structural motifs required for mRNA localization and their interaction with trans-acting protein factors. Russell received an MSc in Intelligent Systems from the University of Aberdeen and his PhD in bioinformatics from the University of Edinburgh. At each of his previous positions, Russell has set up bioinformatics infrastructure including pipelines for next-generation sequencing, RNA structure searches, protein structural modelling and a microscope imaging facility.

Introduction

Advancements in sequencing technologies in recent years have created massive amount of sequenced data, which necessitate the development of efficient computational pipeline to mine the data. Preprocessing of raw next generation sequencing (NGS) data of large genomes such as that of humans is compute intensive. The bioinformatics bottleneck can be more time consuming than the time it takes to sequence the DNA and hence, the application of the right pipeline with features such as ease of setup and use, parallelization, job scheduling and tracking of compute processes is pivotal to move the field forward. To demonstrate and give readers a glimpse on the pros and cons of applying a pipeline to NGS data, this article will take as an example of five human exomes and preprocess them for single nucleotide variant (SNV) discovery. It starts with showing the painstaking process involved in running some common preprocessing software without stringing them together as a pipeline. Then, the application of pipeline for preprocessing in three different ways are discussed: Shell scripting, Galaxy ([Afgan et al., 2016](#)) and eHive ([Severin et al., 2010](#)). Among these three different methods, eHive can be considered as a frontier pipeline or workflow management system that has been deployed for use in big projects such as The Functional Annotation of Animal Genomes (FAANG) ([Andersson et al., 2015](#)). The dataset and software used for this study are given in the Appendix.

NGS Preprocessing

One of the common tasks in resequencing studies is to align raw sequencing data (e.g., provided in FASTQ format) to a genome and then perform variant calling. This process is so common that the literature is replete with examples of methodology that involves preprocessing and there are many different tools that can be used to achieve this purpose. To provide as a sample case study, consider a scenario where researchers have sequenced a human exome using the Illumina technology; what then would be the steps required to go from raw reads to variant calls?

To start the preprocessing, a quality control check on the raw sequenced data is mandatory. A software tool known as FastQC ([Andrews, 2010](#)) can be used for this purpose. A sample command line format is as below:

```
$ fastqc <PE1> <PE2>
```

where <PE1> and <PE2> represents the front paired end and back paired end FASTQ files, respectively. Key aspects such as per base sequence quality, per base sequence content and Kmer content are given as HTML reports for users to evaluate sequence quality ([Andrews, 2015](#)). The presence of adapters is unwanted because only the insert sequences need to be analyzed. Adapters can be removed using Trim Galore! software ([Krueger, 2015](#)).

```
$ trim_galore -paired <PE1> <PE2>
```

The default output from Trim Galore! will be <PE1>_val_1.fq and <PE2>_val_2.fq. For this command with default parameters, TrimGalore! will auto-detect some common adapters such as Illumina universal, Nextera transposase and Illumina small RNA. Users may provide their own specific adapter sequences too. Additionally, by default sequences with quality score below Q20 will also be removed.

Prior to mapping, the reference genome <REF> needs to be indexed for quick access of its sequences, which is done using the command below.

```
$ bwa index <REF>
$ samtools faidx <REF>
```

The mapping of raw FASTQ reads to the reference genome can be done using BWA aligner ([Li, 2013](#)). BWA mem is used in this case because it is more suitable, faster and more accurate for sequences longer than 70 bp. Users can explore other options given in BWA and a myriad of other published aligners but such details are beyond the scope of this article.

```
$ bwa mem <REF> <PE1>_val_1.fq <PE2>_val_2.fq > mapped.sam
```

This is followed by the variant calling step where mapped.sam is the input. SNPs are called using samtools (Li *et al.*, 2009) and bcftools (Narasimhan *et al.*, 2016). The samtools view command converts the alignment file from SAM to BAM format, which represents a more compact way to store the data. Next, the samtools sort command will arrange the mapped alignment according to coordinate in ascending order along the chromosomes in the reference genome. The combination of samtools mpileup and bcftools view is to gather SNPs and visualize in vcf format.

```
$ samtools view -bT <REF> mapped.sam -o mapped.bam
$ samtools sort mapped.bam mapped.sort
$ samtools mpileup -uf <REF> mapped.sort.bam > output.mpileup
$ bcftools view -vcg output.mpileup > result.vcf
```

The vcf output contains all the SNPs found in the sample. However, it is not meaningful if it cannot be translated into biological significance. ANNOVAR (Wang *et al.*, 2010) is a collection of Perl scripts designed for functional annotation of the SNPs. The script converts the vcf format into input recognizable by ANNOVAR. Next, annotate_variation.pl performs annotations on the functions of the SNPs.

```
$ convert2annovar.pl -format vcf4 -includeinfo result.vcf > input.annovar
$ annotate_variation.pl -buildver hg19 input.annovar annovar/humandb -outfile result
```

Upon running the final command, two files will be generated, which are “result.variant_function” and the “result.exonic_variant_function”. The first file contains all the potential gene-based functional annotation of the detected SNPs, and the second file gives additional information regarding the exonic SNPs detected.

Readers should take note that the steps outlined above illustrate some of the important steps for preprocessing but the gold standard version has additional steps such as base quality recalibration. For those interested in a tutorial that details these additional steps, refer in Low and Tammi (2017).

Application of a Pipeline for NGS Preprocessing Automation

Case Study With Shell Scripting

If one would like to perform large-scale analysis of multiple resequenced data, such as human exomes, instead of running commands one by one, users can write a Shell script (*.sh) that encompasses all the above commands. Shell script is a text file that serves as an overall controller for the pipeline of interest. Upon running the script, the written code will be interpreted and the pipeline will then be executed. Some of the usual Shell-script/command-line interpreters are the Bourne shell (sh), C Shell (csh) and the Bourne Again Shell (bash). In the example in Box 1 below, the interpreter used is Bourne shell, as shown by the #!/bin/sh line on top.

This Shell script basically runs the pipeline for the preprocessing steps detailed in the preceding section. The difference is that a script is now being used to chain together a series of commands to process FASTQ files to get variant calls.

In Shell scripting, it is common to add an echo command, which prints out what the next step is, before running a new process. This allows for tracking of analysis progress or errors, and is particularly useful when a long Shell script is used. The input files for the Shell script can be passed from the command line through the usage of arguments/parameters. In this case, the script takes in two arguments, the FASTQ file and the reference genome file. The first argument is passed into the individual commands in the script as \$1, whereas the second argument is passed on as \$2. To ensure that two arguments are always passed into the script, the “if” statement starting at the second line of the script explains the usage, and that the script will automatically quits if there are lesser than two input arguments.

The main advantage of having a Shell script is that it reduces retyping of commands every time similar analysis needs to be carried out, and it can be set to run automatically at scheduled interval using cron (Keller, 1999). As compared to other workflow programs, setting up an analysis pipeline using Shell script has far lesser dependencies as compared to other workflow programs. Additionally, it is easier to customize. However, the disadvantage of this method is that there is no Graphical User Interface (GUI) and some programming skills are required. Furthermore, it is sometimes difficult to troubleshoot errors but this can be helped by writing code that can catch potential errors or trace for errors from log files but the script is not easy to interpret for novices.

Case Study With Galaxy

In the previous section, automation of various preprocessing steps using a Shell script is shown for one human exome dataset. In a real study, it is likely that multiple exome datasets will be used and as such some sort of looping is required to run the same analysis using different FASTQ input and saving the corresponding output. Although a Shell script can still be used for running multiple samples, the complexity of its use may have grown beyond what most can comfortably handle. In this section, a dedicated platform known as Galaxy will be used to demonstrate the same analysis and extending it to include multiple human exome samples.

Galaxy is an open, web-based platform for bioinformatics analysis that is implemented in Python programming language, which can be deployed on any UNIX system, from local computers to clusters to computer clouds. The web-based GUI of Galaxy

uses simple HTML markup that works with most web browsers. It can be accessed via the main public web server (see section Relevant Websites), or other publicly accessible Galaxy servers listed (see section Relevant Websites). It also can be installed locally by following the tutorial: see Relevant Websites section. Galaxy development team has created a portal named Galaxy Community Hub (see section Relevant Websites) that is a forum for discussion and allows researchers to share their analysis workflows.

One of the great features of Galaxy is the point-and-click interface that allows users without programming skills to manipulate data interactively. In addition, Galaxy supports for data uploads from a local computer and also import from external sources (Fig. 1). There are more than 650 tools available in the Galaxy server that enable users to perform a wide range of analyses on their data (Afgan *et al.*, 2016). The Galaxy Tool Shed (Blankenberg *et al.*, 2014) provides a platform where tool developers can share their tool configuration files and documentation (Fig. 2).

Users can create a workflow to string together the flow of output as input in other processes, either by using existing history or from scratch. This is done by using the Galaxy's graphical workflow editor. However, it is recommended that users should plan their analyses in advance if they would like to create the workflow from scratch. Fig. 3 shows the workflow for preprocessing human exome datasets created in Galaxy workflow editor. When the workflow is properly setup, users can run the analysis using point-and-click on the interface. In this workflow, once the exome dataset is uploaded, Galaxy will run FastQC and Trim Galore! concurrently to check the quality and trim the sequences. Next, the output from trimming step will be automatically used as input for mapping to reference genome using bwa, and then call for SNP variants.

Galaxy has the feature of capturing the information of each analysis step, including the datasets, tools and parameters used. Its user interface makes it simple to monitor the status of each job. If a job has failed, the error details will be provided to help in

The screenshot displays the Galaxy web interface. On the left is a 'Tools' panel with categories like 'Get Data', 'Send Data', 'Collection Operations', 'Text Manipulation', 'Filter and Sort', 'Join, Subtract and Group', 'Convert Formats', 'Extract Features', 'Fetch Sequences', 'Fetch Alignments', 'Statistics', 'Graph/Display Data', 'NGS: Mapping', 'NGS: SAMtools', 'NGS: Variant Analysis', and 'NGS: QC and manipulation'. The center panel shows a dataset viewer for a FASTQ file, with a warning that the dataset is large and only the first megabyte is shown. The right panel shows a 'History' panel with a list of jobs, including 'subset10K.SRR5306316.2.fastq'.

Fig. 1 A screenshot of Galaxy interface that shows the uploaded human exome datasets from a local computer. The left panel is a tool panel that contains the list of tools available in Galaxy. The center panel is a detail panel, showing the details of tools and data. The right panel is a history panel, showing the executed jobs and data.

troubleshooting (Fig. 4). The feature of automatically tracked records allows for reproducible research (Sandve *et al.*, 2013), where other users can reproduce the same analysis.

Case Study With eHive

In situations where a large number of NGS datasets need to be processed in a short amount of time, for example, the 1000 Genomes project, a pipeline that is more suitable for heavy tasks is needed. One example is *eHive*, which is a workflow management system designed in Perl. It comes with features such as fault tolerant and distributed processing, which uses schedulers such as Load Sharing Facility (LSF) to submit jobs to the compute clusters (Severin *et al.*, 2010). *eHive* works on the principle that central controller does not perform job scheduling. Rather a queen creates autonomous “worker”, which then create jobs by monitoring the central blackboard.

Report

Fig. 4 A screenshot of Galaxy that shows an example of error messages due to a failed run. The status of jobs is marked by coloured boxes for a quick visualization of the overall run: Grey=in queue, Yellow=currently running, Green=completed, and Red=failed.

As a result, the system “behaves” like an insect hive with workers working on jobs. The advantage of the system is that it has very small (~ 3 ms) job submission overhead. The worker is central to the *eHive* model, once they are created by the *eHive* console, they are registered with the central blackboard. The blackboard will have information about various pipeline analysis, statistics of workers

Fig. 5 A snapshot of an eHive workflow for processing of five human exomes.

registered to different analysis and jobs available for processing. Subsequently, the worker will load the code for a chosen analysis, register it on central blackboard and finally run jobs. Once completed, a worker can create new jobs and post it back to the blackboard for other workers. As workers progress through the processing modules within a job, the processing status is logged on the blackboard. Once a job is completed without errors, the worker will set the job status to “DONE”. The primary strength of the blackboard model is that it provides more flexibility as no central controller is required. Though new workers are created centrally by *beekeeper*, it does not perform task distribution and has no visibility about the structure of the pipeline thus order of which the tasks should be solved. Workers have the liberty to alter structure of the pipeline at run-time and as they are fault tolerant, jobs can be re-executed up to a configurable number in the event of a failure before exiting the pipeline. Moreover, it allows automatic flow of jobs to cluster nodes with higher memory, if there is such a requirement.

Fig. 5 shows data flow of an *eHive* pipeline for the same five chosen human exome datasets mentioned in earlier sections. The “job_factory” is the analysis module, which will discover the raw sequencing data to be processed and create jobs with corresponding parameters (e.g., filenames). The “quality_control” analysis module will run the FASTQC steps for all the jobs in parallel, which upon completion of each will create new jobs for the “adapter_trimming” analysis module. Jobs of “adapter_trimming” analysis module, will start immediately when their corresponding “quality_control” jobs is completed. In other words, the dependency is at the job level instead of the analysis module level, which speeds up the whole processing pipeline. The “reads_alignment” analysis module will perform short reads alignment using bwa and should the computing node runs out of memory due to large dataset, the job will be “passed_on” to the next analysis module doing the same function but executed on a computing node with a larger memory, which in this case is 8 GB. The “func_annotation” module executes the ANNOVAR scripts similar to the above Shell scripting section. By default, each job will have a maximum retry attempt of 4 (configurable), until which the job status will be set to “FAILED.” If a significant number of jobs are failing, the console will be terminated and users can investigate the failed jobs looking at the log messages to fix and resume the jobs as needed. The pipeline can be resumed from the state where the jobs failed using intermediate results if any, and hence removes the need to restart a pipeline from scratch, which is a great time saver especially when failure happens at later stage of the pipeline.

Discussion

The true list of potential ways to run a pipeline is not limited to the three methods outlined. A myriad of other workflow management systems exist and some of them are proprietary software that is beyond the scope here. This article focuses more on the usefulness of a computational pipeline to preprocess raw NGS data that nowadays comes in millions of reads. Whether users prefer to use the

Table 1 Comparison of different methods to automate a pipeline

Feature	Platform		
	Shell Scripting	Galaxy	eHive
Graphical User Interface (GUI) feature	No	Yes	Yes
Ease of setup	Easy, with pre-installed software or tools	Medium, with the advantage of publicly available tools and full integration	Medium
Error logging	Yes but indirect	Yes	Yes
Customization	Flexible	Need more time to incorporate customized scripts into Galaxy	Yes
Suitability for simple tasks	Yes	Yes	Not recommended
Scalable	Yes. Meant for high throughput and large scale analysis	Yes. Assumption is the users manage to set up the run on a cluster or cloud computing infrastructure	Yes. It has been used on projects with large datasets such as FAANG

ubiquitously applied Shell scripting method or resort to a workflow management system, such as Galaxy or eHive, depends on various factors that include complexity of the tasks, users' programming skills, ease of setup, errors troubleshooting and customization. **Table 1** details a comparison of the three pipeline methods and features that users will typically need to consider before choosing any pipeline.

The main reason to use a computational pipeline is to avoid time wastage. In a real biological experiment setting that involves NGS data, such as the human exome example given above, a computational pipeline will likely be designed or utilized by bioinformaticians who can understand instructions from biologists on what analyses need to be carried out. However, bioinformaticians are usually not the system administrator and as such, the pipeline designed is shared with those who understand and manage computer infrastructure to determine efficient ways to run the pipeline. In some projects, such as those that involve proprietary software, a part of the pipeline is essentially a 'black box' to the users and critical time bottleneck may not necessarily be in the pipeline itself but rather in the communication on how the data was processed. Sometimes even data transfer itself is time consuming, such those involving large alignment file in BAM format generated by a company that is in a country different than that of the user, who needs to be a custodian of such files for subsequent analyses. Efficiency from raw data to outcome requires consideration of external factors, such as data communication and transfer.

Conclusion

A computational pipeline is necessary to achieve efficiency in preprocessing of high throughput sequencing data, especially when dealing with multiple samples. The application of the right pipeline depends on complexity of the tasks, users' programming skills, ease of setup, error troubleshooting, customization and scalability.

Acknowledgement

We thank M. Farhan Sjaugi for his help on eHive installation.

Appendix

Sample Exome Datasets and Software

The human exome data was downloaded from the NCBI Sequence Read Archive (SRA). Here is a list of the SRA IDs: SRR3270888.sra, SRR5182389.sra, SRR5280052.sra, SRR5306316.sra, SRR866988.sra.

The FASTQ files can be obtained using NCBI SRAtoolkit as per sample commands:

```
$ ./sra toolkit.2.8.1-3-centos_linux64/bin/prefetch -v SRR5215189
$ ./sra toolkit.2.8.1-3-centos_linux64/bin/fastq-dump SRR3270888.sra -split-files
```

The software included in this study are given below:

- FastQC version 0.11.4 for quality control check of FASTQ files. The software is available at Babraham Bioinformatics website (see section Relevant Websites).

- Trim Galore! Version 0.4.4, downloadable at Babraham Bioinformatics website (see section Relevant Websites). This software served as automation of adapter and quality trimming of raw FASTQ sequences.
- BWA version 0.7.12 (see Section Relevant Websites). This software maps the raw NGS reads against a large reference genome (e.g., GCRH37, Hg19). BWA could map not only short reads (up to 100 bp) but also long reads (up to 1 Mbp). It uses the Burrow-Wheeler Transformation (BWT) algorithm for mapping reads. The input of BWA is a FASTQ file and the output is either a SAM or BAM file.
- Samtools version 0.1.18 (see section Relevant Websites). This software provides useful utilities to work with SAM and BAM files. It allows users to view, sort and make index of the BAM/SAM files. In addition, it is also possible to call variants by using mpileup and bcftools.
- ANNOVAR (version 2016 Feb01) is a program built for functional annotation of genetic variants acquired from NGS data and it is written in Perl. To download it, users need to register at ANNOVAR website.
- IGV version 2.3.72 is a visualization tool for SNVs data developed by the Broad Institute, which can be obtained at Integrative Genomics Viewer website.

Genome Annotation: Perspective From Bacterial Genomes

Alan Christoffels and Peter van Heusden, University of the Western Cape, Cape Town, South Africa

© 2019 Elsevier Inc. All rights reserved.

Introduction

Advances in sequencing technologies have accelerated the generation of genomic data for a myriad of species in record time. The Genomes Online Database (<https://gold.jgi.doe.gov/>) GOLD provides comprehensive access to information regarding genome and metagenome sequencing projects, and their associated metadata. For example, as of 1st May 2018 the GOLD database contained 10,204 completely sequenced bacterial genomes. Access to these genomic resources allow scientists to compare genomes in different biomedical, environmental and/or geographical contexts and driving the development of comparative and visualization tools that underpin the field of comparative genomics. Therefore, it is important to accurately define the location and structure of genes in a genome and map these at different levels to proteins, function and pathways.

Genome annotation refers to the extraction of biological information from nucleotide sequencing data. Medigue and Moszer (2007) define a two-component hierarchy for genome annotation; namely, (i) a static view of genome annotation versus (ii) a dynamic view of genome annotation.

Static View of Genome Annotation

A range of gene prediction tools is used to predict the location of a gene (i.e., protein coding region or functional RNA). The predicted genes are used in sequence similarity searches against databases to assign a cellular function to the gene product. Functional assignment includes chemical and structural properties of proteins, sub-cellular localization, biological functions in a cell and protein domain identification.

Caveats to this approach

Gene prediction tools can miss small genes or genes with unusual nucleotide composition. For example the smallest gene identified is 39 nucleotides long PatS peptide (Yoon and Golden, 1998), yet gene prediction algorithms avoid such a short gene length parameter setting to optimize its performance (Tripp *et al.*, 2015). Furthermore, genome sequencing projects could be incomplete i.e., draft assembly and contain sequencing errors that will impact the accuracy of gene prediction tools.

Protein function assignment through sequence similarity search uses a similarity threshold score to limit spurious results. Accuracy of the annotations is improved by using annotations of model organisms that are manually curated; such as, data in RefSeq (Pruitt *et al.*, 2007) and UniProt (The UniProt Consortium, 2007).

Protein domain identification could lead to a single domain being shared by two unrelated proteins. The overall protein domain organisation is required to remove false positive functional assignment.

Dynamic View of Genome Annotation

The annotations obtained in Section “1” are enriched for biological context by integrating information at the level of regulatory and metabolic networks, and protein-protein interactions. Chromosome context is also used to improve genome annotations especially when sequence identity is low. For example, co-location genes in different genomes, gene order and gene fusion analysis allows for more accurate assignment of orthologues. These co-localized genes tend to be co-expressed and can provide evidence for protein interactions that feed into reconstruction of protein interaction networks. Annotations stemming from integrated information can be accessed through warehouses that facilitate exploration of the data via queries against a range of annotation attributes (O'Malley and Soyer, 2012; Triplet and Butler, 2011). Intermine (Smith *et al.*, 2012), is a framework that allows construction of such warehouses. More recently this framework was used as the bases for INDIGO – an Integrated data warehouse for microbial genomes (Alam *et al.*, 2013).

Genome Annotation Software

Genome annotation pipelines vary in their degree to which they are automated. Initial development of annotation pipelines included MAGPIE (Gaasterland and Sensen, 1996), GENEQUIZ (Hoersch *et al.*, 2000), AUTOFACT (Koski *et al.*, 2005), and BASys (Van Domselaar *et al.*, 2005). The latter is a web-based system for annotating bacterial chromosomes. Many of these tools do not allow users to edit the underlying annotations. Often editing applications are independent of the annotation database. For example, annotation and editing browsers such as ARTEMIS (Berriman and Rutherford, 2003) and Apollo (ref) provide a platform for reviewing and editing annotations but do not generate the annotations. Instead the annotations are imported from a GFF formatted file or database.

A combination of automated and manual annotation platforms include commercial systems such as ERGO (Overbeek *et al.*, 2003) or Pedant-Pro (successor of PEDANT (Frishman *et al.*, 2001)), and open-source systems, such as GenDB (Meyer *et al.*, 2003), Manatee (TIGR, unpublished), SABIA (Almeida *et al.*, 2004) and AGMIAL (Bryson *et al.*, 2006). Many of these annotation tools have other dependencies or the annotation pipeline requires a range of tools to be stitched together so that inputs and outputs are clearly defined. The installation of an array of tools (Fig. 1) required for annotation pipelines have been simplified with the availability of the conda package manager and the bioconda package channel. A package channel is a collection of precompiled software packages that can be installed by conda. The bioconda project creates conda packages for bioinformatics software, released through the conda package channel of the same name.

Curated Data Repositories for Genome Annotation

Data collections provide the basis for comprehensive genome annotation. These databases can be categorized as follows:

- (1) Nucleotide Resources
The International nucleotide sequence database collection (see “Relevant Websites section”) is a collaboration among DDBJ, EMBL and GENBANK. Other resources such as RefSeq (Pruitt *et al.*, 2007) at NCBI provide a non-redundant integrated set of nucleotides and proteins for a range of organisms.
- (2) Protein Resources
UniProt (The UniProt consortium, 2007) originated from a merger between SwissProt and PIR protein databanks. This resource represents an expertly curated annotation resource, inclusion of the relevant literature and numerous cross-references. The unprecedented volume of data that required curation had to be further sub-divided into two collections namely:
 - (i) UniProtKB/SwissProt – manually validated protein entries, and
 - (ii) UniProtKB/TrEMBL – computationally annotated records
- (3) Protein domain Resources
InterPro (Finn *et al.*, 2017) provides a unified resource that links databases such as PFAM (Finn *et al.*, 2016) and Prosite (Sigrist *et al.*, 2013). These proteins are organized into protein families based on their protein domain signatures.
- (4) Cluster of orthologous groups
Proteins are clustered based on BLASTP comparison of all proteins against all. Clusters are generated if a minimum of three distantly related organisms are present (Tatusov *et al.*, 2003).
- (5) Metabolic Pathways
These are provide by KEGG (Kanehisa *et al.*, 2017) and BioCyc (Karp *et al.*, 2015).

Fig. 1 Integrated Genome Annotation Pipeline.

- (6) Protein interactions
STRING database integrates predicted and known protein interaction data (von Mering *et al.*, 2007).
- (7) Structural databases
PDB (Berman *et al.*, 2007) stores 3-D protein structures.

Stepwise Approach to Genome Annotation

Genome annotation is preceded by a process of genome assembly using a reference genome-based method or de novo approach. The annotation of the assembled genome (Fig. 1) starts with identifying and masking RNA genes using RNAmmer (Lagesen *et al.*, 2007) and tRNAScanSE (Schattner *et al.*, 2005). Gene finding tools; such as, Prodigal (Hyatt *et al.*, 2010), GeneMark (Besemer *et al.*, 2001) and MetageneAnnotator (Noguchi *et al.*, 2008); are used to identified open reading frames (ORFs) in the genome sequence. These ORFs are BLAST searched against databases such as GENBANK and UniProt to identify putative functions and protein evidence. The ORFs are mapped to metabolic pathways using a KEGG database. Protein domains are identified through InterProScan searches. This search assigns GO terms to each of the protein domains and these features are later used to carry out functional enrichment analyses. ORFs are searched against the conserved domain database (Marchler-Bauer *et al.*, 2013) that includes COGs to identify corresponding orthologs.

Future Directions

In 2017 the NCBI announced that they would be re-annotating the 89732 bacterial genomes available in the Genbank repository using a new version of their automated prokaryotic genome annotation pipeline (PGAP). Analysis of the set of non-redundant proteins derived from this annotation exercise yielded a set of automated annotation rules that allow for rapid application of the best possible annotation for novel proteins (Richter and Rosselló-Móra, 2009). The future of prokaryotic genome annotation will almost certainly involve the application of curated biological knowledge for the development of heuristics for such multi-level annotation rules. Even these rules, however, only allow annotation of some 53% of the prokaryotic proteins in ReqSeq.

One obstacle facing annotators of de-novo assembled prokaryotic genomes is the difficulty in accessing expertise of biocuration communities, such as the one contributing to the NCBI rule engine described above. Historically the worlds of automated genome annotation and manual curation of annotation have been far apart. The emergence of rule engines (and possible in the future machine learning (Yip *et al.*, 2013) promises to accelerate the work of curators and bring the two worlds of annotation closer together.

Improved automated pipelines (e.g. Prokka (Seemann, 2014) and DFAST (Tanizawa, 2018)) and acceleration of pipeline components such as homology search tools (e.g. RapSearch (Ye *et al.*, 2011), DIAMOND (Buchfink 2014) and GHOSTX (Suzuki, 2014)) are addressing the need for faster annotation which in turn is driven by the decline in cost and increase in volume of DNA sequencing.

While there have been web-based portals for prokaryotic genome annotation available for more than a decade (e.g. MaGe (Vallejo *et al.*, 2006), RAST (Aziz *et al.*, 2008) and the many others mentioned in Siezen *et al.* (2010) advances in package deployment (e.g. conda) and the Galaxy web-based science platform (Afgan *et al.*, 2016) now make it possible to make prokaryotic genome annotation tools available “in house” to users who might not be familiar with the command line.

Closing Remarks

The decreasing cost of sequencing drives the production of genomic sequencing data such that genome annotation continues to be a requirement to provide biological context. Improving the accuracy of genome annotation, the process of extracting biological information from nucleotide sequencing data, requires a combination of ab-initio gene finding tools, supporting experimental evidence and manual curation. Adhering to such an integrated genome annotation strategy will allow scientific enquiry based on a rich source of meta data.

Biographical Sketch

Alan Christoffels After completing my studies in South Africa in 2001, I moved to Singapore for a postdoc with a focus on genome evolution. During this time I contributed to the annotation and genome analysis of the Pufferfish genome and developed method for detecting genome duplication events. This methodology was later used in other international genome projects after I established my laboratory in Singapore in 2004. In 2007 I returned to South Africa and established my group at the University of the Western Cape at the South African National Bioinformatics Institute. For the following 8 years, I was part of an international execute team driving the genome sequencing and analysis of the Tsetse genome. As of 2013, the focus of the lab has shifted to bacterial genomes where most of my funding is directed at *M. tuberculosis*. My bioinformatics laboratory focuses on building tools and analyzing data that leads to a better understanding of human-M. tuberculosis interaction with a focus on functional non-coding RNA, drug target identification and genome evolution. Underpinning these Tuberculosis projects are methods to analyze next generation sequencing data.

Peter van Heusden I first joined the South African National Bioinformatics Institute as a computer systems administrator in 1996 and was soon involved in assisting with the bioinformatics research of the Institute. In the past decade I have assisted with annotating the genome of the African coelacanth (*Latimeria chalumnae*) and that of the Asian sea bass (*Lates calcarifer*). Since 2014 I have led a research software engineering team at SANBI with a focus on automating scientific workflows, specifically those related to analysis *Mycobacterium tuberculosis* genomic data.

Next Generation Sequencing Data Analysis

Introduction

The era of next generation sequencing (NGS) began following the first reports of this innovative technique in 2005 (Margulies *et al.*, 2005; Shendure and Ji, 2008). The high-throughput NGS technology, which uses parallel amplification and sequencing yields shorter read lengths, giving an average raw error rates of 1%–1.5% (Shendure and Ji, 2008) when compared to conventional Sanger sequencing protocols, which can generate to 1000 bp of 99.999% per base accuracies. While automation attempts of traditional dideoxy DNA sequencing by Sanger method improved the efficiency of DNA sequencing; however, in terms of cost and time, NGS technology was regarded as superior. An early method called massively parallel sequencing (MPS) that was introduced by Lynxgen Therapeutics set the stage for high throughput sequencing (Brenner *et al.*, 2000). The first NGS machine, the GS20, that was made available for researchers in 2005 by 454 Life Sciences (Basel, Switzerland) is based on large-scale parallel pyrosequencing by microbeads in micro-droplets of water in oil emulsion (Henson *et al.*, 2012).

The major NGS technology platforms in the market for whole-genome sequencing are primarily from brand names such as Illumina, Roche 454, Solid and IonTorrent. Each platform has its advantages and disadvantages and cost implications in terms of reliability, time and money (Table 1). Depending on each NGS platform, they offer values that may be attractive for specific purposes. For instance, the Ion Torrent is often positioned as a general purpose sequencer as well as in diagnostic protocols due to the quicker turnaround time (Tarabeux *et al.*, 2014). However, longer reads technology offered by Illumina and Roche are desirable but the cost involved for Roche 454 FLX is very steep rendering it impractical for large scale genome projects. Reads from Pacific Bioscience machine, PacBio, are generally not used in large genome projects for direct sequencing but can be useful in resolving repetitive regions and ambiguous regions due to capability of generating very long read lengths (Table 1).

NGS Process Workflow

The common processes involved in general NGS platforms are library preparation, library amplification, and sequencing (Figure 2.3). The starting material for library preparation can be from either RNA or DNA (genomic source or PCR-amplified). In the case of RNA, it has to be transcribed into cDNA because as of now, NGS machines sequence only DNA directly. Since target library molecules sequenced on each NGS platform are required to be in specific lengths, genomic DNA requires fractionation and size selection, which is performed by sonication, nebulization, or enzymatic techniques followed by gel electrophoresis and excision. For instance, Illumina NGS platform's standard fragment size is in the range of 300 and 550 bp including adapters. Generally, libraries are built by adding NGS platform-specific DNA adapters to the DNA molecules. These adapters facilitate the binding of the library fragments to a surface such as a microbead (454, Ion PGM, SOLiD) or a glass slide (Illumina, SOLiD).

However, depending on the specific NGS platform, the library construction step has to be customised to fit the sequencing protocol. Generally, DNA library construction directly depend on its applications and can be divided mainly into fragment libraries and mate-paired libraries. In fragment libraries, target genomic sequences are fragmented to smaller sizes typically up to 5 times the NGS platform's read length capabilities. Subsequently, sequencing adapters are attached to these fragments allowing the NGS platform to sequence from the adaptor tags. Typically, fragment libraries are of single end and paired-end. With adaptor tags at both forward and reverse sites, NGS platforms are able to sequence from both ends in paired-end libraries. The applications of fragment libraries are mainly for variant calling, copy number detection and genome reconstruction. While other types of NGS

Table 1 Comparison between different NGS platforms

	454 FLX	HiSeq2000	Solid 5500XL	IonTorrent (318 Chip)	PacBio
Company	Roche	Illumina	Life technologies	Life technologies	Pacific biosciences
Nucleotides/Run	700 Mbp	540–600 Gbp	180 Gbp	800 Mbp	0.5–1 Gbp
Maximum read length	700 bp	2 × 100 bp	75 + 35 bp	200 bp	10 kbp–> 40 kbp
Pairs	2 × 150 bp	2 × 150 bp	2 × 60 bp	N/A	
Run time	23 hours	11 days	12–16 days	4.5 hours	30 m–4 hours
Reagent cost per Mbp (USD)	7	0.04	0.07	1	0.13–0.60
Advantages	–Read length –Fast	–High throughput –Read length	–Low cost/base –Accuracy	–Less expensive –Fast	–Read length –Fast
Disadvantages	–Expensive –Homopolymer errors –Low throughput	–High DNA concentration –Short reads	–Slow –Palindromic errors –Short reads	–Homopolymer errors	–Error rate

sequencing techniques may exist, the fundamental principles are similar in fragment library construction. Other techniques may involve intermediary steps such as fragment capture, immune-hybridizations or reverse transcription.

In mate-pair library construction, target DNA sequences are fragmented to size more than 1000 bp that are often longer than the read length capacities of the NGS platforms. The required fragment size is excised from a gel electrophoresis run of the sheared DNA corresponding to the intended library size usually 2 kbp, 5 kbp or 10 kbp. These isolated DNA fragments are circularised by ligation through addition of biotinylated adapters to the ends to promote sequence specific ligation instead of ligating across fragments. Once again, the circularised DNA are fragmented and biotinylated fragments are purified by affinity capture. Sequencing adapters are added to the size selected sequences. The manipulation performed during the library construction step allows identification of the terminal sequences of the circularised DNA by sequencing. Having known the sequence length *a priori*, computational algorithms can help differentiate large scale genomic rearrangements from a reference sequence besides typically being used to guide the scaffolding process in a genome assembly.

In the sequencing step, having known adaptor sequences allows the amplification of library fragments either by emulsion PCR (emPCR) or bridge PCR which are methods specific to the NGS platforms. Commonly, irrespective of platforms, NGS exploits parallelism in a factor of ten thousand to billions of library fragments. Generally, this is achieved by reiterated cycles of nucleotide addition using DNA polymerases or ligases (SOLiD), detection of incorporated nucleotides and washing steps. The extensive washing and repetitive steps, albeit automatic, may thus take sequencing to complete from hours to days. Base calling is the process of algorithmically deciding the incorporated nucleotide from the signal intensities that are detected during sequencing process.

Every NGS platform relies on slightly different strategies to generate and detect signals (Luo *et al.*, 2012; Merriman *et al.*, 2012; Ronaghi *et al.*, 1998). For instance, the chemistry used by Illumina and SOLiD sequencing is similar to the principles of sequencing by synthesis. Using four separate fluorescent-labelled nucleotides, its flushed over the glass slide and fluorescence signals are repetitively captured when nucleotides become incorporated to target sequences. In contrast, flooding of non-labelled nucleotides in 454 and Ion PGM sequencing are detected by pyrophosphate or proton release as part of its unique chemistry. Typically, the proton release is measured as a pH change by the semiconductor chip of the Ion Torrent instrument (Merriman *et al.*, 2012). On the other hand, pyrophosphate signal in the 454 system relies on chemistry of the enzyme luciferase to induce light signals (Ronaghi *et al.*, 1998). Altogether, these signals respective to each platform will be converted into basecalls and converted into raw sequencing data that is generally output in FASTQ format that includes the basecall qualities along with the DNA sequence.

While many platforms exist, markedly there are many advantages of NGS, compared to the conventional Sanger sequencing, such as: (i) NGS permits a considerably higher degree of parallelism than Sanger's conventional capillary-based sequencing. (ii) Removal of bottlenecks and limitations in older methods (*E. coli* transformation and colony picking) by *in vitro* construction of a sequencing library, followed by *in vitro* clonal amplification further enforcing parallelism in the workflow (iii) NGS system usually uses reagents that operate on immobilized target on arrays in microliter quantities, which costs are gained back over the full set of sequencing features on the array because the volume per feature are in the range of picoliters to femtoliters. Overall, these advantages translate into intensely lower costs for DNA sequence production using NGS technologies (Shendure and Ji, 2008). Therefore, in any NGS projects, the high-throughput nature of the method is favoured (Figs. 1 and 2).

Typical Data Analysis Workflow for NGS

NGS analysis utilize bioinformatics approaches in order to convert signals from the machine to meaningful information that involve signal conversion to data, annotations or catalogued information, and actionable knowledge. Primarily, the NGS bioinformatics analysis is divided into three distinct phases as primary, secondary and tertiary analyses. In the primary analyses, raw data from the sequencers are converted into nucleotide base and short read data. Secondary analyses apply detailed bioinformatics methodology specific to the NGS technique that was employed which may involve read alignments or read assembly. Usually, secondary analyses have the most complex analyses workflow and is usually run in a sequence as a pipeline. Besides, depending on the type of NGS technique that are employed, the analysis pipeline may differ greatly. For example, RNA-seq data, which characterizes transcriptomes, differ in secondary analysis approach compared to ChIP-seq data, which investigates genome-wide epigenetic mechanisms. Lastly, by tertiary analyses, the previous results obtained can be associated and understood in a biological context. However, tertiary bioinformatics analyses can be an iterative process that involve rigorous statistical and computational biology methods.

Sequence Generation

The initial primary analysis is usually transient as the sequencing machines detectors receives the signals obtained from the high throughput reactions. Thus, the base-calling and recording process is tightly integrated with the sequencing instruments resulting in quality scores corresponding to the short reads nucleotide sequence being output parallelly. The primary analysis software is installed by machine vendors on the workstation supporting the sequencing instrument. The software can be run in high-performance cluster systems for faster results. Besides converting raw signals to base calls, some software tools include demultiplexing of multiple samples into a single pooled and indexed run (Dodt *et al.*, 2012).

Fig. 1 Schematic diagram of the process involved in common NGS platforms. Adapted from Knief, C., 2014. Analysis of plant microbe interactions in the era of next generation sequencing technologies. *Plant Genet. Genom.* 5, 216. Available at: <https://doi.org/10.3389/fpls.2014.00216>.

NGS Raw Data Pre-Processing

As described earlier, NGS platforms suffer from higher error rates compared to Sanger sequencing (Nakamura *et al.*, 2011; Shendure and Ji, 2008). However, as part of primary analysis, different approaches and algorithms have been developed to compensate and spot these errors (Margulies *et al.*, 2005). Moreover, bases that have inaccuracy less than 0.1% can be carefully chosen algorithmically. As a simple approach, error-rates can be decreased by performing the DNA sequencing with high coverage, of at least 20–60-fold, depending on the sequencing project's goal (Luo *et al.*, 2012; Margulies *et al.*, 2005; Voelkerding *et al.*, 2009). Notably, each sequencing read can be categorised as a distinct genotype but in fact could be the result of sequencing error. Thus, it is very important to use established methods in differentiating these two causes of variation as it may lead to inaccurate results when flawed.

Fig. 2 Workflow of NGS data analysis in three phases: primary, secondary and tertiary. The tertiary phase of Comparison and Discovery is indicated as an iterative process.

To improve the quality of the data after base-calling, Phred-based filtering algorithms can be used to filter or remove low quality sequencing reads (Margulies *et al.*, 2005). These filters discard reads with low-quality, uncalled, and ambiguous bases besides clipping the lower quality 3'-ends of reads. All such filters use the quality information contained in the FASTQ file that are computed by the NGS platform at each base during the base calling procedure. Previous studies (Minoche *et al.*, 2011) have shown the effect of different filtering approaches on Illumina data and suggests that it can reduce error rates to less than 0.2% by eliminating around 15%–20% of the low-quality bases, mostly via 3'-end trimming that are prone to errors. Another study has supported the findings that a 5-fold decrease of error rate can be observed by applying a filter (Phred score of Q30, with 0.1% likelihood of a false basecall) that eliminated reads with low quality bases (Nguyen *et al.*, 2011). It may be useful to note that low quality bases are sometimes localised in specific regions of a genome. It is important to note that removal of these reads may introduce potential bias in the quantitative studies undertaken (Minoche *et al.*, 2011; Nakamura *et al.*, 2011). Therefore, read clipping strategy can be used to remove the erroneous bases from the left or right edges of the reads without filtering the whole reads in order to address errors that are usually present in the reads edges alone.

Apart from read clipping and filtering methods, several error correction tools (e.g., Coral, HiTEC, Musket, Quake, RACER, Reptile, or SHREC) could be used as a complementary strategy to reduce sequencing error rates in reads (Knief, 2014). Generally, these error correction methods make use of high sequencing coverage in order to identify and correct errors using the laws of probability and statistics. Moreover, these algorithms often consider quality scores of the examined bases besides looking at neighbouring base quality values. For instance, some of these tools are able to correct substitution errors in Illumina sequencing data (Ilie and Molnar, 2013; Liu *et al.*, 2013; Yang *et al.*, 2010) while others (Coral, HSHREC, KEC, and ET) are designed to include indel correction algorithms that are available for the analysis of Roche's 454 and IonTorrent data (Salmela, 2010; Salmela and Schröder, 2011; Skums *et al.*, 2012). The relevance of error correction tools is seen as a very useful strategy in *de novo* genome sequencing, resequencing and amplicon sequencing projects with benefits ranging from finding more optimal assembly in the DBG and reducing overall memory footprint to perform the assembly stage (Skums *et al.*, 2012; Yang *et al.*, 2010).

Genome Assembly

After the pre-processing of sequence reads, we can assemble the pre-processed reads into contigs. The process of assembly of sequencing reads generated from NGS technology involves the reduction of redundant data by contiguously placing reads by overlapping them adjacent to each other in an optimal way (Miller *et al.*, 2010). Instead of reads, when contigs (assembled set of reads) undergo the previously described process with long length information, it is known as scaffolding. In other words, it is a process of reconstructing the target as such to groups reads into contigs and contigs into scaffolds.

Generally, the size and accuracy of the contigs and scaffolds are important statistics in genome assemblies (Miller *et al.*, 2010). The quality of genome assemblies is usually described by maximum length, average length, combined total length, and N50. The contig N50 is the length of the smallest contig in the set that contains the fewest (of the largest) contigs whose joint length represents at least 50% of the assembly (Miller *et al.*, 2010). Generally, larger N50 values imply a higher quality genome assembly that describes lesser overall fragments. Typical high-coverage genome projects have N50 values that range in megabases; however, they are dependent on the genome size and is not a good measure to compare between unrelated assemblies instead of the same. Assembly accuracy is tough to quantify. Nevertheless, mapping the assembled contigs/scaffolds to reference genomes is useful to examine its quality if the references exist.

As outlined earlier, an assembly is an ordered data construction that maps the sequencing data to a supposed reconstruction of the target (He *et al.*, 2013). Contigs are reconstructed sequences from sequence alignment of reads which give rise to a consensus sequence. The scaffolds is a higher order organisation of sequences which define the contig order and orientation and the sizes of the gaps between contigs. The scaffolds represent more contiguous sequences mimicking the physical genome composition. Scaffold sequences could have N's in the gaps between contigs. The number of consecutive N's may show the gap length estimate during the assembly process based on the bridging of mate pair reads (Miller *et al.*, 2010).

There are many well-established software for assembling sequencing reads into contigs/scaffolds. In general, these genome assemblers can be grouped into three categories based on their approaches (Miller *et al.*, 2010): (1) The Overlap/Layout/Consensus (OLC) approaches depend on an overlap graph; (2) the *de Bruijn* Graph (DBG) use some form of *k*-mer graph; and, (3) the greedy graph algorithms can use OLC or DBG (Table 2).

There are many factors that need to be considered when choosing the most appropriate genome assembler especially when considering for large whole genome sequencing project. Among these factors are the choice of algorithm, compatibility with the NGS platform, the support of the assembly of large genomes, and parallel-computing support for speeding-up the assembly (Zerbino and Birney, 2008). Generally, the choice of algorithm and software will directly determine the memory requirements and speed of assembly. In general, DBG assemblers are faster but require large amount of memory compared to OLC assemblers.

Read Mapping

Whenever a reference genome becomes available, instead of a *de novo* assembly strategy, reads are mapped or aligned to the reference genome prior to subsequent analysis steps. The goal of mapping is to realign the vast number of reads back to the respective regions it likely originated from. The mapping of the reads to the reference genome typically involves the alignment of millions of short reads to the genome using fast algorithms. The algorithms are able to function parallelly while taking into account mutations such as polymorphisms, insertions and deletions in order to produce the alignment. In well-known aligners, for example BLAST, the individual query sequence is searched against a reference database using hash tables and seed and extend approaches. With NGS data, often similar methods are adapted to scale the alignment of short query sequences that are in the millions against a single reference genome of large sequences. Advances in mapping algorithms using various other techniques has improved alignment speed while reducing memory and space requirements. Examples of mapping software that are well known and used in NGS data includes SOAP2 (Short Oligonucleotide Alignment Program), BWA (Burrow-Wheels Alignment), NovoAlign and Bowtie 2.

The widely used format of storing mapping information of the reads to the genome is SAM (Sequence Alignment Map) format or its compressed binary form called BAM. While the BAM file is smaller and optimized for machine reading, the SAM file is human readable albeit slower for computer operations. There are 11 mandatory fields in the SAM format specification. Commonly, SAMtools software is used to manipulate and read both BAM and SAM formats.

Typically, mapping of reads to the reference genome is followed by collecting data about the mapping statistics. The summary statistics that is mainly of interest is the percentage of aligned reads, or the mapping rate. The mapping rate of reads to the reference genome are usually only 60%–75%. Besides the limitation due to the intrinsic properties of NGS data and technique that it was generated from, the inability to map to the reference genome can be ascribed to challenging regions in the genome, such as repeat rich regions, that aligners are not able to map to. Moreover, short read lengths in most high throughput NGS technology limits the alignment in mapping to span a small region hence limiting its coverage to convenient areas of the genome. Besides that, limitations such as NGS sequencing error, algorithmic robustness, mutational load and variation contributes to the low mapping rate.

The mapping file generated can be further inspected by regional in-depth using visualization tools such as genome viewers which plot pileups (the stacked alignment of the reads). Visualization of reads mapped, for instance, can be important in diagnosing problems in read alignment in certain regions, detecting duplicates, and visualizing variations. Commonly used genome browsers that enable the reading of SAM files include Integrated Genome Viewer (IGV), and Tablet while some web-based browser that achieve similar visualizations include JBrowse, NGB and UCSC genome browser.

Table 2 Summary of assembly software used for *de novo* assembly of genomes

Assembler	Algorithm	Preferred data	Multithreading	Target genome
SGA	OLC	Illumina	Yes	Large
SOAPdenovo2	DBG	Illumina	Yes	Large
ALLPATHS-LG	DBG	Illumina	No	Large
CLC	DBG	Mixed	No	Large
SSAKE, SSHARCGS and VCAKE	Greedy	Illumina	No	Small
Edena	OLC	Illumina	No	Small
Newbler	OLC	454	No	Large
CABOG	OLC	Mixed	No	Large
Euler	DBG	454 + Sanger	No	Small
Velvet	DBG	Illumina	No	Small
ABYSS	DBG	Illumina	Yes	Large

Tertiary Analysis

The tertiary process of analysing NGS data can be quite diverse depending on the scenario and context of a study. Generally, the reads that are representative of the underlying annotations will characterize the functional aspects of the study. As such, the corresponding statistics used are usually descriptive. In other cases, where a comparison is being made to a reference or a control, rigorous statistical tests are employed taking into account read counts in the target regions representative in each treatment groups. Applying statistical models to identify bias, accounting covariates and testing for significant difference are common steps in comparative analysis. The resulting outcomes of the analysis may provide a collection of target annotations or genes. Such a gene list can be subsequently analysed for enrichment in regards to gene ontology (GO) terms to infer the collective function, biological process and cellular compartmentalization. With such a gene list, the pathways being affected can also be mapped to grasp a better biological understanding of the process. In other derivative NGS techniques such as ChIP-seq or Hi-C, tertiary analysis may additionally involve deriving profiles that are commonly occurring in the interactions being observed. Thus, new motifs, structural interactions and regulatory signals that are being generated for a particular condition can be characterized. NGS techniques when applied to a population could derive meaningful interaction of evolutionary forces besides characterizing the differences in genetic composition either in terms of polymorphisms when observing the same species or taxonomy when studying metagenomics.

Conclusion

Approaches to NGS data analysis are diverse and dependant on the technology and methods being employed. Nevertheless, among the multiple stages that are involved in NGS data analysis, steps in primary and secondary analysis is generally a prerequisite in all NGS projects. Therefore, primary and secondary analyses must be carefully performed in order to prevent errors being carried over to tertiary analysis. In tertiary analysis, insights can be generated from the inclusion of annotation, network, and interaction information from external databases to expand on gene lists and profiles found in earlier steps. Collectively, these steps are required frequently, hence, independent bioinformatics labs create analysis pipelines for their in-house routine analyses. However, as NGS technology grows and improves, the methods for analyses may require further evaluation and integration with latest technologies.

Glossary

Alignment The process of mapping reads to a reference genome.

Complex diseases Otherwise known as multifactorial disorders. Contrast to Mendelian diseases, these diseases are caused due to multiple genes or mutations as well as environmental risk factors.

Germline variants Variants or mutations present in the germ cells.

Mendelian diseases Disorders caused due to mutation at a single locus and are inherited according to Mendel's law.

Reads The short sequence of nucleotide bases from a single molecule of DNA detected by the sequencers.

Somatic variants Variants exclusive to somatic cells and not present in germ cells.

Variant calling Variant calling refers to identification of bases in the sequencing reads which are different from the reference genome at that position.

Whole exome sequencing Sequencing only the protein coding region of an organism's genome.

Whole genome sequencing Sequencing the complete genome to identify the full DNA sequence of an organism.

Introduction

The human genome is composed of three billion base pairs, comprising both protein coding and non-coding regions. The advancement in sequencing techniques from traditional Sanger sequencing to massively parallel high-throughput methods has made genome sequencing faster, cheaper, and more informative, allowing for a more comprehensive understanding of human genetics. Genome sequencing has become a vital clinical tool for the identification of the genetic basis of diseases, facilitating the management and treatment of many previously intractable conditions. There are two primary methods used to identify particular allelic variants in a given individual: Whole Genome Sequencing (WGS) and Whole Exome Sequencing (WES). WGS involves the sequencing of the entire genome, while WES focuses specifically on sequencing only the coding (exonic) regions of the genome in a more targeted approach. Both methods provide an unbiased means of variant identification to identify variants making them invaluable tools for precise personalized medicine.

The human exome comprises the entirety of the protein coding portion of the genome, which is just 1%–2% of the entire genome. The term exon derives from EXpressed regiON, i.e., the regions that are translated into protein products. These are generally the best studied and understood regions of the genome, and any mutation therein has the potential to disrupt normal protein function and to thereby cause disease. Given its more focused approach to genomic characterization, exome sequencing has emerged as a powerful tool in the recent years and has been utilized successfully to identify several severe and rare diseases associated with specific genetic variants in protein coding regions. The list of such diseases includes Miller Syndrome (Ng *et al.*, 2010b), Schinzel-Giedion syndrome (Hoischen *et al.*, 2010), Nonsyndromic hearing loss (Walsh *et al.*, 2010), Perrault syndrome (Pierce *et al.*, 2010), Sensenbrenner syndrome (Gilissen *et al.*, 2010), Kabuki syndrome (Ng *et al.*, 2010a), Progeroid syndrome (Puente *et al.*, 2011) and many others, each of which is caused by distinct mutations in specific proteins with serious physiological consequences. Exome sequencing thus provides a revolutionary means of characterizing the genomic landscapes of individuals with single base resolution, facilitating the identification of disease-associated mutations that allow for a more in-depth understanding of the root causes of a given disease, ultimately facilitating its treatment and management.

Background

There are two unbiased sequencing-based approaches for detecting genetic variations in an individual: Whole Genome Sequencing (WGS) and Whole Exome Sequencing (WES). While the human genome contains 3 billion bases, the human exome contains only 30 million bases (30 Mb). Despite phenomenal improvements in the accuracy and economic viability of genomic sequencing technologies, sequencing whole human genomes to a depth sufficient to identify novel variants associated with a given disease phenotype remains prohibitively resource-intensive both in terms of monetary and computational costs. WGS approaches are thus primarily employed for variant identification and related discoveries only in large genome sequencing laboratories and companies where such an approach is financially viable.

Advantages of Whole Exome Sequencing

WES technologies, in contrast, have helped to significantly reduce the time and resources required for actionable data – 20 human exomes can be sequenced in the same time required to sequence a single human genome. WES analysis significantly reduces the computational burden relative to a WGS analysis owing to the 99% reduction in the size of the sequenced regions within a given individual. Protein coding regions are better conserved between individuals (and across species) relative to intronic and non-coding regions, as the vital role of proteins in all aspects of human physiology renders these regions significantly more sensitive to the potentially deleterious effects of mutations. Indeed, more than 85% of disease-causing mutations in Mendelian diseases are located in coding regions of the genome. Given this enrichment for disease-associated mutations within the exome, WES provides an unbiased yet targeted approach to detect these variants, facilitating personalized and precision medicine at a fraction of the cost of WGS.

Exome Sequencing Analysis Workflow

The complete exome sequencing workflow begins with the extraction of DNA from a donor or patient of interest, and ends with the biological interpretation of identified variants through both experimental and computational approaches. The initial wet lab procedures involved in exome sequencing include genomic DNA extraction, DNA fragmentation, adaptor ligation, targeted exome capture, enrichment, and finally sequencing. The subsequent computational protocol involves the processing of raw sequencing reads to obtain a Variant Call Format (VCF) file that contains the list of identified variants within the given individual's exome. Intermediary steps include read quality control, alignment of sequenced data to a reference genome, post alignment clean-up (such as removal of duplicate reads), indel realignment, and base quality score recalibration, followed by variant calling, filtering, and annotation of the identified variants. Several in-depth guides regarding library preparation and sequencing are available in various published articles, and are an ideal resource for individuals performing WES (Parla *et al.*, 2011; Teer and Mullikin, 2010; Zhang *et al.*, 2015).

To begin a whole exome sequencing-based experiment, following the development of a careful experimental design which takes into account optimal patient/donor numbers and means of enriching for individuals with novel disease-associated variants, samples (blood, cheek swabs, etc.) must be collected from relevant individuals. After DNA is extracted from these samples, it is subjected to random fragmentation either via ultrasonication or with the help of transposons. Ensuring random fragmentation is important to avoid introducing sequencing artifacts. Artificial DNA linkers are added to the ends of all fragments to generate a shotgun library. Fragments containing coding sequences are then captured and enriched by commercially available hybridization-based capture kits. This target enrichment can be performed using in-solution or array-based capture techniques. For in-solution enrichment, a variety of probe definitions are available from different commercial companies such as Agilent, Illumina and NimbleGen. These enrichment strategies primarily differ in their specific genomic target regions covered, size, number of probes, and in their workflow design (see Table 1). The fragments of interest are hybridized to biotinylated DNA or RNA baits (depending on the exome capture kit used). The hybridized fragments are later recovered and enriched via affinity-based pull down, and are amplified prior to sequencing in order to generate a library of only captured exons.

Sequencing of the enriched fragments can be performed using a range of different sequencer platforms commercially available from Illumina, Life Technologies, or PacBio's SMRT. The information regarding the base identified at a particular position is stored in a raw data output file, the format of which varies based on the sequencer chosen. Regardless of the utilized sequencer, these files can be processed and analyzed using the data analysis pipelines tailored to answer experimental questions of interest. The steps of data analysis, starting from raw sequencer file outputs, are described further below.

Exome Sequencing Analysis

Quality Control/Pre-Processing

Sequencer outputs are known as nucleotide base calls, and are stored in the form of short nucleotide sequences called reads in file formats that vary based on the sequencing platform chosen. Generally accepted formats for read files are FASTQ and SRA (Sequence Read Archive). A number of different criteria can be used to assess read quality, including by measuring average read quality scores, GC content, presence of contaminating sequences and/or adaptor sequences, overrepresented k-mers, duplicated reads, and PCR artifacts.

Table 1 Exome capture platforms for human exome sequencing

	<i>NimbleGen's SeqCap EZ exome v3.0 kit</i>	<i>Agilent's sure select human all Exon V6 kit</i>	<i>Illumina's TruSeq exome prep kit</i>	<i>Illumina's Nextera rapid capture exome and expanded kit</i>
Probe size (bp)	55–105	114–126	95	95
Probe type	Biotinylated DNA	Biotinylated cRNA	Biotinylated DNA	Biotinylated DNA
Coverage strategy	High-density, overlapping probes	Adjacent probes	Gaps between probes	Gaps between probes
Fragmentation method	Ultrasonication	Ultrasonication	Ultrasonication	Transposons
Target region size (Mb, human)	64	60	45	62
Genomic DNA input required	1 ug	100 ng	100 ng	50 ng
Hybridization time (hours)	72	16	16	16
Reads remaining after filtering	66%	71.7%	54.8%	40.1%
Major strengths	● High sensitivity and specificity ● Most uniform coverage in difficult regions	● Better coverage of indels ● High alignment rate ● Fewer duplicate reads than other platforms	● Good coverage of UTRs and miRNAs	● Good coverage of UTRs and miRNAs
Major weaknesses	● More duplicate reads than Agilent ● Lower alignment rate than Agilent	● Fewer high-quality reads than NimbleGen	● High off-target enrichment	● High off-target enrichment ● Coverage bias for high GC content areas reducing uniformity
Human support	Not required	Not required	Required	Required

The quality of a given base call is measured as a Phred quality score and indicates the probability of the base being called correctly. The scores generally range from 2 to 40 with higher scores indicating greater confidence in the call. A common practice is to filter out bases with Phred scores below 20, although individual preferences may lead some researchers to modulate this threshold. The removal of redundant reads and undesired sequences (such as 3' adaptors, contaminants, or primers) is essential as contaminating sequences will not align to the genome resulting in poor alignment quality. Trimming low quality ends from reads is important as current sequencers are highly error-prone, with a significant dip in base quality at the 3' ends of reads. With time it is likely that such technical issues will be resolved, allowing for even more cost-effective whole exome sequencing.

Other pre-processing alternatives include assessing the read GC content. A uniform GC content across reads signifies good sequencing without artifacts or contaminants. Contaminating sequences are identifiable by checking if the frequency of a k -mer (a short sequence of bases of length k) is unusually high relative to levels that would be predicted due to chance. Sequences matching known adaptor sequences should be trimmed before aligning the reads to a reference genome, as mentioned above.

It is necessary to carefully examine the quality of raw reads prior to alignment in order to obtain a high percentage of properly aligned reads. FastQC ([Andrews, 2010](#)) is a commonly used application that can examine the quality of read sequences. It reports several parameters such as sequence quality scores, GC content, length distribution, and duplication levels. Cutadapt ([Martin, 2011](#)) and Trimmomatic ([Bolger et al., 2014](#)) are readily available programs that allow for the detection and trimming of adaptor sequences in reads, facilitating downstream alignment and analysis.

Reference-Based Alignment

The next step following quality control is alignment of reads to a reference genome. For human samples, this process involves the matching of short sequences of bases to a published reference genome using an alignment program. This is a complex and computationally intensive task, as the software ultimately matches millions of short sequences to 3 billion possible positions within the reference genome. Successful alignment requires the utilization of an effective alignment algorithm that is both efficient at searching for perfect base matches as well as tolerant of imperfect matches. This latter consideration is particularly important, as the goal of whole exome sequencing is to identify novel single nucleotide polymorphisms (SNPs), which by definition will be distinct from those incorporated into the human reference genome. Such considerations also allow the algorithm to identify insertions or deletions within the genome that could also have physiological consequences. Computationally the algorithm must be fast, memory efficient, and strike an effective balance between accuracy and speed. These tools must also be capable of handling single end and paired end reads, as paired end reads are the most common approach to sequencing data generation. Based on the computational approach used for quick and memory efficient string matching, aligners can be broadly classified into hash-based method or Burrows-Wheeler Transform (BWT) method ([Table 2](#)). Hash-based methods create hash table either for the read sequences or for the reference genome and use them to identify the matches. Aligners such as SOAP ([Li et al., 2008b](#)), MAQ

Table 2 Commonly used alignment algorithms

Aligner	Description
Borrows-Wheeler Aligner (BWA)	Gapped alignment based on Borrows-Wheeler Transform. Consists of three algorithms: BWA-backtrack, BWA-SW, and BWA-MEM. BWA-MEM is the most recent and efficient algorithm among the three.
Bowtie (1 and 2)	Both Bowtie 1 and 2 are ultra-fast memory efficient aligners based on Borrows-Wheeler Transform. Bowtie 1 is short read (≤ 50 bp) and ungapped aligner while Bowtie 2 allows gaps and has no restriction on read length.
SOAP (1,2 and 3)	While SOAP 1 is hash-based method, SOAP 2 and 3 are based on Borrows-Wheeler Transform. SOAP 2 is more memory efficient and utilizes lesser time than SOAP 1. SOAP 3 is the recent version which uses GPU processors.
MAQ	It is an ungapped short read aligner. It creates hash indexes of reads and scans the reference against the hashes to detect matches.
ELAND	Developed by Illumina company, it one of the first short read aligners. It performs ungapped alignment for reads of size 32bp. However, additional Perl scripts are provided to overcome the limitations. The source code is freely available for the machine buyers.
SHRiMP (1 and 2)	Performs Smith-Waterman local alignment algorithm for both letter space and colour space reads. While SHRiMP 1 indexes the reads, SHRiMP2 indexes the genome and is much faster. SHRiMP 2 also allows paired-end reads alignment and utilizes multi-threaded computation.
Novoalign	A commercial tool from Novocraft. It performs alignment by hashing the reference genome and is also capable of adaptor trimming and base quality trimming. It allows gaps and mismatches up to 50% of read length.

(Li *et al.*, 2008a), ELAND, and SHRiMP (Rumble *et al.*, 2009) are hash-based. BWT-based methods create a data structure called FM index for the genome sequence using data transformed using BWT and suffix array of the sequence. Popular aligners based on this approach are BWA (Li and Durbin, 2009), Bowtie2 (Langmead and Salzberg, 2012), and SOAP3 (Liu *et al.*, 2012).

Once generated, alignment results containing the read sequences and their respective mapped locations on the reference genome can be stored in the human readable format known as Sequence Alignment/Map (SAM) or in the Binary Alignment/Map (BAM) binary format (Li *et al.*, 2009). These alignment results then undergo further quality control, assessed based on a number of parameters including percentage of aligned reads, mapping quality, alignment scores, number of mismatches, and percentage of uniquely aligned reads. Successful mapping of 70%–90% of reads to the reference genome indicates good overall sequencing accuracy and absence of substantial amounts of contamination, thereby allowing for proper downstream analyses.

Several groups have reported on the comparative advantages of distinct aligners (Li and Homer, 2010; Fonseca *et al.*, 2012; Flicek and Birney, 2009). These tools differ based on their sensitivity, speed, and indexing approach. Choosing the right aligner and optimal parameters based on the sample is vital for high quality alignments, as errors could be carried downstream to variant calling. However, depending on the specific experimental application being employed there may be more than one effective alignment algorithm available. For this reason it is important that individual investigators discuss the advantages and disadvantages of each aligner prior to choosing the one which they ultimately utilize.

Post Alignment Processing

To ensure the quality of identified genetic variants in sequenced and aligned samples, several optional post alignment processing steps can be performed. These include removal of PCR and other duplicates, local alignment around indels, and recalibration of base quality scores.

Removal of Duplicates

The initial steps of library preparation involve the shearing of DNA, ligation of adaptors to both ends of the sheared fragments, and amplification of these fragments via PCR. PCR amplification is performed in order to obtain enough target DNA for sequencing with good depth and coverage. This approach can, however, selectively amplify certain DNA fragments leading to PCR duplicates and an overall misrepresentation of the initial genetic sample. Such a biased selection can lead to a disproportionate amplification of a single allele while ignoring the other, resulting in incorrect allele identification. As a consequence it is necessary to remove these PCR duplicates before variant calling in order to avoid any bias in calculation of variant frequency. While polymerases used in modern PCR reactions are of high fidelity, there is inevitably a chance that any PCR reaction may also introduce novel mutation errors during amplification. These PCR artifacts are difficult to distinguish from true DNA content solely on the basis of sequence and alignment information, as it can be difficult to tell a novel variant apart from an *in vitro* PCR-induced mutation.

Programs such as SAMtools (rmdup) (Li *et al.*, 2009) and Picard Tools (MarkDuplicates) can be used to remove the duplicates *in silico* so that they do not adversely affect sequence analyses or variant identification. These programs identify duplicates using information on the orientation and exact start site location on the forward and reverse read at their 5' and 3' positions respectively to properly establish whether a read is a duplicate or not. While SAMtools retains only the read with the highest mapping quality score, discarding their duplicates, Picard Tools simply sets a different flag for the highest scoring read pair and does not discard any

reads from the file (Ebbert *et al.*, 2016; Li *et al.*, 2009). As with other software packages, experimental need and investigator preferences will inevitably drive appropriate software selection.

Local Realignment (Indel Realignment)

Sequencing reads are mapped to the reference genome independently of one another during alignment. As a result, there are a large number of erroneous alignments that typically accumulate around the locations of indels (insertions/deletions) or low complexity regions. The next step is to locate genomic regions containing indels and to improve their alignment quality. Indel alignments to the reference genome create gaps due to their novelty, and as a consequence of poor alignment they are prone to noise. Local realignment is one solution that can help improve the accuracy of these reads. In this procedure, the reads around the indels are realigned based on the alignment information of other reads present in the location or by local *de novo* assembly of all reads spanning the indel region along with construction of a consensus sequence for indel discovery. This provides a better chance to accurately align indels than does aligning them solely based on a reference genome, which will not be able to account for these novel sequences. Although this is an optional procedure, it is still advisable to perform realignment to obtain high quality variants, given that these are the desired outcome of most whole exome sequencing studies. Programs that perform indel realignment include IndelRealigner (GATK) (Mckenna *et al.*, 2010), Dindel (Albers *et al.*, 2011), and Novoalign.

Base Quality Score Recalibration (BQSR)

Each base called by the sequencing platform is assigned a Phred score which indicates the confidence of the base call to be error-free, as discussed above. This automated system, however, generates scores that are error-prone as they can be over- or underestimated due to systematic errors. Although imperfect, Phred scores remain an important criteria for accurate variant calling, as bases with a low score still have a high probability of being called incorrectly. As variant callers depend greatly on the confidence of the base call, it is necessary to reconfirm the accuracy of the quality scores. BQSR is a process that applies machine learning to empirically model the errors and correct them accordingly, thereby markedly improving the accuracy of quality scores and boosting the quality of subsequent variant identification.

During recalibration, a covariation model based on the data and a set of known variants is constructed. Feeding in information on known variants will prevent the calling of real variant bases as base call errors. This covariation model is built based on quality score, position within the reads, and neighbouring nucleotides. Second, the base quality of the remaining mismatched bases are corrected based on this newly built model. It is common practice for investigators to generate before and after BQSR plots in order to visualise changes in base scoring for quality control purposes. Some commonly used tools are Recab (NGSUtils suite) (Breese and Liu, 2013), BaseRecalibrator (GATK) (Mckenna *et al.*, 2010), and ReQON (Bioconductor package) (Cabanski *et al.*, 2012).

Variant Analysis

A variant can be defined as a base in an individual's genome that is not the same as that in the reference genome. Variant calling refers to the identification of these mutated bases in the aligned reads, highlighting points that differ from the reference genome. To be called as a variant the base must have a good quality score and be well supported by multiple reads, thus minimizing the chance that the read is the result of poor alignment or other technical issues. Genomic variants or mutations can be of different types such as Single Nucleotide Variants (SNVs), insertion and deletion variants (indels), Copy Number Variants (CNVs), and large Structural Variants (SVs). The origin of these mutations may be either germline or somatic in nature. Germline variants, present in germ cells, are inherited and often related to familial diseases. Somatic mutations are often associated with tumour development, and are not heritable. The output of variant calling programs is a file containing several records, each of which represents a specific variant. Variant analysis consists of three major steps: Variant calling, annotation of variants, and prioritization of variants of interest depending on the constraints of a given study.

Variant calling

Variant calling refers to identification of bases in the sequencing reads which are different from the reference genome at that position. Variant calling can be performed using either single samples or multiple samples simultaneously depending on the experimental design and availability of computational resources/time constraints.

Germline variant calling

Germline variants correspond to the SNVs and indels in germ line cells. Briefly, germline variant calling tools compare each position of the sample genome to the reference genome and mathematically model the allele counts to obtain the genotype likelihood measures. Programs for identifying germline variants include UnifiedGenotyper (GATK), Haplotype caller (GATK) (Depristo *et al.*, 2011), FreeBayes (Garrison and Marth, 2012), SAMTools (Li *et al.*, 2009), Atals2 (Evani *et al.*, 2012), and VarScan 2 (Koboldt *et al.*, 2012).

Somatic variant calling

Somatic variants refer to the acquired mutations in somatic cells and are not transmitted to the progeny. As somatic variants play an important role in tumour initiation, development, and migration, somatic variant calling is widely used in cancer research and personalized medicine. It is highly recommended to have samples of both tumour and normal tissue/cells from a given patient in order to precisely identify only somatic variants while discarding the germline variants present in a given individual. Somatic variant calling programs detect variants using joint diploid genotype likelihoods or shared allele frequency between samples. Tools for somatic variants identification include MuTect (Cibulskis *et al.*, 2013), Strelka (Saunders *et al.*, 2012), deepSNV (Beerenwinkel *et al.*, 2015), and VarScan 2 (Koboldt *et al.*, 2012).

Variant annotation

Once variants are identified, they are annotated with attributes such as associated genomic features including tissue-specific expression, transcription factor binding sites, eQTLs, gene symbol, exonic function, and the specific amino acid change in question to facilitate the interpretation of their potential functional impact. Several tools are available for annotation of variant positions using information compiled from publicly available databases. They can also be used to calculate minor allele frequency (MAF) in normal populations, mine experimental evidence from clinical assays, predict potential deleterious variant functions, and analyze the frequency of the variant in oncogenic genes. Tools for annotating the variants are ANNOVAR (Wang *et al.*, 2010), MuTect (GATK), SnpEff (Cingolani *et al.*, 2012b), SnpSift (Cingolani *et al.*, 2012a), and VAT (Wang *et al.*, 2014), with ANNOVAR and MuTect being the most commonly used tools.

Variant filtration and prioritization

Typically a variant calling analysis will produce a list of thousands or millions of variants. This means that in addition to annotation, it is necessary to filter this list to obtain high confidence target variants that contribute to the disease or biological process under study. Variants are selected based on population frequency, coverage, supporting reads, and alignment score. They can also be prioritized according to their predicted coding effect. Mutations that are likely to cause a loss of protein function such as nonsense mutations in conserved regions, splice mutations that lead to frameshift, and mutations that alter protein structure are often disease-causing variants. Disease-causing mutations can be identified based on experimental evidence from previous studies or by observing specific mutational patterns present in the pedigree of affected and unaffected individuals. Some tools available for prioritization include VAAST2 (Hu *et al.*, 2013), VarSifter (Teer *et al.*, 2011), KGGseq (Li *et al.*, 2012), gNOME, PLINK/SEQ, and Ingenuity Variant Analysis.

Complete Automated Pipelines

A major challenge for most laboratories after sequencing is the management of data in a structured, systematic manner for targeted computational analysis. The WES analysis pipeline requires the use of many different tools for different analysis steps, and its complex parameters need to be optimized for every run. As a consequence, advanced skills and a complete understanding of the tools available, their usage, as well as their relative advantages and disadvantages, is required. Data manipulation and interpretation of the results after each step in the processing pipeline is a potentially overwhelming task for inexperienced users.

The complexity of exome sequencing data analysis can be simplified by software suites which provide all tools required for each step of this processing pipeline in a unified package. Several WES data analysis pipelines are available in the public domain. SIMPLEX (Fischer *et al.*, 2012) is a cloud-based pipeline for single-end (SE) and paired-end (PE) exome sequencing data analysis available from Illumina and ABI SOLiD. SeqMule (Guo *et al.*, 2015) is a Linux-based, user-friendly pipeline for analyzing exome and genome sequencing data. It integrates five alignment and five variant calling algorithms to provide comprehensive analyses. It can be used for identifying both somatic and germ line variants and allows for comparison of results from the different included algorithms. This platform is very flexible, as it allows users to modify the configuration file in order to fine tune its parameters. Fastq2vcf (Gao *et al.*, 2015) is another open-source pipeline that incorporates several open-source tools that allow users to perform analyses from quality control of reads to variants annotation. Galaxy (Afgan *et al.*, 2016), an open source online platform, has a wide collection of tools integrated. Customizable WES pipelines can be created and executed online. Many commercial tools are available with automated WES analysis pipelines, such as CLC Genomics Workbench 9.5.3 by Qiagen, STRAND NGS by Strand Life Sciences Pvt. Ltd which can be installed locally and their modules can be updated by connecting to their servers as per user requirements. Ingenuity Variant Analysis software Ingenuity Systems provides analysis toolkit which directly connects to its database for analysis. Other commercial software programs include Partek and DNA nexus.

Repositories for Variant Storage and Annotation

The critical step in linking mutations to disease is the identification of rare pathogenic variants which are responsible for a disease of interest. This is generally achieved by filtering out known variants present in normal healthy individuals. Such filtering is done with the help of repositories which maintain databases of such variants. Some of the widely used repositories for such common variants are the Single Nucleotide Polymorphism database (dbSNP) (Sherry *et al.*, 2001) and the Exome Aggregation Consortium (ExAC) (Lek *et al.*, 2016). Also of note, the Online Mendelian Inheritance in Man (OMIM) (Hamosh *et al.*, 2005) is the largest repository of known pathogenic variants reported for human.

dbSNP database

dbSNP is the largest repository for simple single nucleotide variants, containing both disease causing mutations and neutral polymorphisms. The Reference SNP (refSNP) Cluster Report on each variant contains the location, sequence, alleles, experimental conditions, population frequency, and variant view. Links to several external databases such as HGBASE, TSC (The SNP Consortium, Ltd), variation initiative, and NCI CGAP-GAI are also available. The ANNOVAR tool can be used to annotate the list of variants with dbSNP and filter out the neutral variants and those with minor allele frequencies greater than 1% to obtain a comprehensive list of target variants.

ExAC database

A key challenge when identifying actionable mutations is that every individual carries several thousand mutations which may not be responsible for disease and are generally seen in a subset of healthy individuals. The ExAC database maintains the largest publicly available repository of human exomes representing populations around the world. Exomes of 60,706 individuals have been deeply sequenced and mined for variants in a uniform fashion. The ExAC browser can be used to mine actionable mutations by eliminating commonly occurring background mutations in the variant dataset.

OMIM database

OMIM is a continuously updated repository of human genes and their associated phenotypes, with a focus on the molecular relationships between genetic variation and phenotypic expression. The information available at OMIM is sourced from literature and is used to identify phenotypes associated with specific human genes. The data uses Mendelian Inheritance in Man (MIM) identifiers and provides concise information on a given gene's location, structure, function, available animal models, and relevant references.

Applications of Exome Sequencing**Discovery of Rare Variants in Mendelian Diseases and Complex Disorders**

Exome sequencing has emerged as one of the most efficient strategies for deciphering the genetic causes of both simple Mendelian diseases and complex disorders. It has helped to link several diseases with their causal genes or variants, providing a cost-effective and high-throughput approach to relevant variant discovery. This approach can thus lead to deeper understanding of the mechanisms of disease, leading to improved diagnosis, and the development of superior preventive strategies or targeted therapeutics.

To identify causal variants, two types of exome sequencing sampling strategies are used: family-based sequencing and extreme phenotype sequencing. When multiple members of the same family are affected with a trait, then exome sequencing is performed for the most distantly related individuals. Distant relatives share fewer common genetic variants and hence allow identification of pathogenic variants with a greater amount of confidence. Sequencing a parent-offspring trio in which only the offspring is affected can also be conducted to identify variants responsible for complex diseases. The extreme phenotype sampling strategy involves sequencing the extreme phenotype samples of a trait i.e., samples on the either ends of a phenotype distribution (such as individuals with the most severe forms of a disease and normal controls). Alleles contributing to the extreme phenotypes are enriched, facilitating identification of causal variants.

Mendelian disorders arise from single mutations or a small number of mutations in select causal genes. Many studies have shown that exome sequencing can be successfully applied to discover causal genes in rare Mendelian disorders. The first such successful application of exome sequencing was the identification of the genetic root of the rare Mendelian Miller syndrome (Ng *et al.*, 2010b). Exome sequencing of four affected individuals was performed, and the mutations on the responsible gene, DHODH, were discovered after filtering the exonic variants of the affected individuals against dbSNP and eight HapMap exomes.

Complex disorders are thought to be linked with single or multiple genes and/or a confluence of genetic and environmental risk factors. This results in a heterogeneity of both phenotypes and of the genes and factors involved, necessitating additional scrutiny when performing WES. Exome sequencing of large numbers of patient samples still makes such variant identification possible owing to its reduced costs relative to WGS, and its concomitant reduced analysis burdens. A successful application of WES for a complex phenotype was employed in the case of peripheral neuropathy in two male siblings born to healthy parents exhibiting this disease phenotype. Upon WES analysis, the causal mutation was revealed to be the deletion or substitution of arginine in the 1070th position on the PRX gene. This mutation is known to cause Dejerine-Sottas syndrome, or peripheral neuropathy (Williams *et al.*, 2016). WES has also identified a number of causal genes for complex traits such as mental retardation (Vissers *et al.*, 2010) and sporadic autism spectrum disorders (O'Roak *et al.*, 2011).

Cancer is a heterogeneous disease with each tumour carrying a range of distinct somatic mutations in a number of different oncogenes and tumour suppressor genes including SNV's, short indels, copy number variants, and gene translocations. This makes it a challenge to identify causal genes in cancer. The success of the Human Genome Project bolstered interest in understanding cancer exomes. The first cancer exome study analyzed 140 human acute myeloid leukemia (AML) WES samples and identified six known and seven novel mutations relevant for AML pathogenesis (Ley *et al.*, 2003). Another early cancer exome study cataloged the landscape of genetic alterations that occur during tumorigenesis by studying the exomes of 11 colorectal and 11 breast tumors. They observed few recurrently mutated genes and several rarely mutated genes (Wood *et al.*, 2007). This demonstrates the powerful

capabilities of WES-based approaches in the context of complex disease, enabling the identification of potential novel driver mutations of cancer and underscoring the clinical utility of this tool.

Clinical Diagnosis

The success of WES in identifying genetic causes of disease has paved the way for its application as a diagnostic tool utilized for unbiased personalized medicine. Currently in a clinical setting WES is being used as a diagnostic tool for identifying casual genes and variants in patients afflicted with diseases that are suspected to be Mendelian in nature. It can also be used to identify dormant risk variants in patients even when symptoms are unobservable, particularly in patients with a family history of a given genetic disease. WES combined with pedigree information, through literature and relevant database searches, has been critical for diagnosis and variant or casual gene discovery in cases related to congenital heart disease, autism, epilepsy, brain malformation, neurodevelopmental deformities, and other neurological or congenital conditions.

Discussion Limitations of Exome Sequencing

As with every technology, exome sequencing also has limitations, and failure to identify disease-associated variants can occur for many reasons. One potential impediment to such analyses is the lack of knowledge of the full human transcriptome, due to an incomplete understanding of the exact locations of all protein coding regions. This makes comprehensively defining targets for WES challenging. Some of the technical reasons underlying potential assay failure include poor efficiency of capture probes, insufficient sequencing efficacy, and poor selection of target for sequencing. Analytical challenges include inadequate coverage at the casual variant location, identification of variants in low complexity regions, false positives due to misaligned reads, and poor separation of casual and non-casual alleles. Although the majority of known diseases are caused by mutations in the protein coding regions of genes, intronic regions are important and can also contribute to disease in certain instances. WES by definition precludes the possibility of identifying structural variants that arise in intergenic or intronic regions or on mitochondrial chromosomes.

Despite these limitations, WES remains a vital tool in clinical diagnostics due to its relatively low monetary and time costs relative to other sequencing approaches. As sequencing costs continue to decrease, computational resources become more available, and algorithms become more efficient it will inevitably become standard to perform WGS to establish gene-phenotype relations. Until technological advances permit for this approach, WES is a powerful tool that captures much of the utility and functionality of whole genome sequencing.

Future Directions

Advancements pertaining to Sequencing technology and large scale data analysis and management will significantly push the limits of exome sequencing applications. Improvements in sequencing methodologies will lead to production of longer reads, detection of longer indels, fewer errors during base call, high quality sequences and reliable reference genomes. With the decreasing costs and turnaround time for sequencing, usage of reference genomes specific to geographical population, ethnicity, etc., will become feasible thereby eliminating the use of a single reference genome during variant discovery. Additionally, integrated approach of WES and WGS will be increasingly applied to complement the short comings of the individual methods. Apart from WES and WGS methods, NGS is applied to other omics of cell such as the transcriptome, epigenome, proteome, and metabolome. It has already been recognised that integration of multi-omics data is crucial to get a holistic understanding of the disease state and its systems biology and multi-omics data integration will slowly become a routine in the foreseeable clinical space. With advent of NGS, there has been an enormous influx of data, making omic data handling and management undoubtedly one of the major challenges. The increasing data has led to the creation of global repositories for easier access. Efforts are also being made to create repositories with reliable multidimensional annotation and curation of phenotype. Parallel advancements in the fields such as artificial intelligence/machine learning, high performance computing and large scale data analysis will play major roles in data mining and knowledge extraction of sequencing data. Accordingly, we can look forward to a future where the current challenge of identifying of new Mendelian disorders and their causative genes will be easily resolved due to the collective effort, immense technological developments and progressive interdisciplinary research.

Closing Remarks

The field of genetics has witnessed remarkable progress in the past decade owing to the advancement in sequencing technology and computer science. With decreasing costs and increasing application of sequencing, whole exome sequencing has become an irreplaceable tool in the clinical space, giving faster, cheaper, and reliable results. However, translating the acquired knowledge in the clinical space is one of the biggest challenges being faced. A collective effort is required from researchers all around the globe to solve all Mendelian disorders, decipher the phenotype-genotype relationship, understand the disease mechanism and its systems biology which will ultimately translate the knowledge into better diagnostics and therapeutics.

Biographical Sketch

Anita Sathyanarayanan is pursuing her PhD in Bioinformatics at Queensland University of Technology, Australia. Her current area of research is application of computational methods to multi-omics data to understand cancer development and progression. Her research interests centres around the intersection of machine learning and high-throughput omics.

Srikanth Manda has completed his Masters in Biotechnology from Indian Institute of Technology, Bombay, thereafter, pursued a PhD in Bioinformatics from Institute of Bioinformatics, Bangalore and Johns Hopkins University, USA. During his PhD work he has analyzed datasets from Whole Genome (WGS), Whole Exome (WES), Transcriptome, epigenome, miRNAome, proteome and phosphoproteome. His research interests involve multi-omics data analysis, integration and interpretation from high-throughput platforms using available tools and cloud based workflows.

Mukta Poojary is a graduate student at CSIR-Institute of Genomics and Integrative Biology (CSIR-IGIB), New Delhi. She is a recipient of Bioinformatics National Certification (BINC). She works in the area of Genome informatics. Her academic interests spans RNA biology, Population genomics, Pharmacogenomics and Multi-omic data analysis.

Shivashankar H Nagaraj is Advanced Queensland Research Fellow at Queensland University of Technology. The focus of his group is on the development and application of bioinformatics approaches that utilize large amounts of data to solve problems in Genomics and Proteomics. He has developed multiple Bioinformatics solutions (e.g., ESTExplorer, EST2Secretome, PGTools) that are valuable and of practical utility to the wider scientific community.

Whole Genome Sequencing Analysis

Introduction

The development of DNA sequencing has revolutionized the biological sciences and facilitated the discovery of gene functions. The first widely used DNA sequencing method was Sanger sequencing (Sanger *et al.*, 1977; Slatko *et al.*, 2001) developed in the 1980s in a manual way. Rapid shifts in the techniques of DNA sequencing made it possible for automated sequencing in the 1990s, which allowed the sequencing of whole genomes (Heather and Chain, 2016). Whole genome sequencing (WGS) is a laboratory process that determines the entire DNA sequence of an organism's genome at once. It involves uncovering the order of bases in a complete genome of an organism, which is backed by automatic DNA sequencing methods and computer techniques to assemble the tremendous biological sequence data (Sarawathy and Ramalingam, 2011). Whole genome shotgun sequencing was already in use in 1979 for small genomes ranging from 4000 to 7000 base pairs (Staden, 1979). In 1995, the first genome of *Haemophilus influenzae* was sequenced (Fleischmann *et al.*, 1995). Later, the sequencing of nearly an entire human genome was completed in 2000 (Lander *et al.*, 2001). However, early techniques for WGS were slow, labor-intensive, and expensive, especially in the era of extensive growth of genomic data (Kwong *et al.*, 2015).

The advent and widespread use of next generation sequencing (NGS) techniques have greatly brought about the availability of whole genome analysis and significantly enhanced the capacity to perform efficient and low-cost WGS. Generally, NGS processes contain massively parallel sequencing, where millions of fragments of DNA from a single sample are sequenced (Moorthie *et al.*, 2011). At the cellular level, it has been applied to the resequencing of previous reference strains and allows for the identification of all the potential mutations in an organism at the genomic level (Schuster, 2008). The genes in a genome usually don't work independently and their functions are not directly controlled by the promoter but rather many other regulatory elements such as the response elements, enhancers, and silencers (Sarawathy and Ramalingam, 2011). Therefore, the implementation of WGS will not only present better understanding of the function of all the genes in the cell, but also characterize the related information of DNA that is involved in gene expression. In addition, compared with whole exome sequencing (WES), WGS provides much more comprehensive information on genes by sequencing the noncoding DNA, which captures 98%–99% of the genome; most of the information about the function of noncoding DNA is still a mystery.

The power of NGS has broadened the scale of many applications in current work, including genetic variation (Dalca and Brudno, 2010; Alkan *et al.*, 2011a,b), assembling new genomes or transcriptomes (Flück and Birney, 2009), quantitative RNA-sequencing analysis (Pepke *et al.*, 2009), epigenetic change identification (Meaburn and Schulz, 2012), etc. In this article, we only discuss the aspect of WGS application for processing genomic data related to genetic variation. The types of genetic variants mainly consist of single nucleotide polymorphisms (SNPs), indels (insertions or deletions), structural variants (duplications, deletions, and inversions), and copy number variants (CNVs) (Zafar *et al.*, 2016; Hillier *et al.*, 2008; Kidd *et al.*, 2008). The inherited variation raises a great deal of risk for individual health that may cause both common and rare disease (Andrew *et al.*, 2017). WGS renders multiple potential solutions by providing full-scale collection of genetic variants. Though the expense to conduct a large scale has decreased considerably, there is still much space for the reduction of the cost that could popularize the techniques and applications of WGS. Consequently, it is necessary to develop more advanced and efficient methodology and pipelines for processing and analyzing whole genomes.

Typical Computational Pipeline of Whole Womene Sequencing

The exponential growth of NGS data has promoted the blossom and release of tools for genomic analysis in recent years. Numerous different workflows are now available to deal with high-throughput genome sequencing data in the distinct types (Leipzig, 2017), for example, shell script, tool-specific interface, and graphical workflow environment (Wang *et al.*, 2009; Yoo *et al.*, 2011; Goecks *et al.*, 2010; Chard *et al.*, 2008). A typical computational pipeline for WGS usually contains components such as data preparation, alignment and assembly, variant calling, annotation, and analysis. Fig. 1 shows the detailed steps of the pipeline for WGS analysis.

Data Preparation

The first step in the pipeline of WGS is data preparation, more specifically, sample preparation. The samples of nucleotide vary greatly from source to quality, which requires professional kits that help to acquire the nucleic acid after purification processing. To obtain the sequences, the genomic materials need to be managed into a sample library that contains short fragments after purification (Van Dijk *et al.*, 2014). The sample libraries usually require high quality and intact sequences at a sufficient amount that meets the requirements for performing the sequencing by instruments (Wong *et al.*, 2012). The general procedures of library preparation consist of several steps. The first step is to split the source genomic material into required lengths and then conduct the end repair and ligation of oligonucleotide adapters to the ends of the fragments. Next is the enrichment of the adapter ligated

Fig. 1 A typical computational pipeline for whole genome sequencing.

library, and the final process is the validation and quantification of the results. Once the library construction is completed, large volumes of samples are sequenced in parallel by sequencing tools. The output of sequencing will be regulated in a standardized format such as FASTQ for alignment.

Alignment and Assembly

Once WGS data has been prepared, the alignment is set up that maps the reads of these samples to a reference genome. The length of reference genome could alter from thousands to billions of possible positions based on the species, so comparing plenty of short nucleotide reads to the reference genome is computationally intensive and time consuming (Kwong *et al.*, 2015). The implementation of alignment is usually using one or more specific algorithms aiming at the sequence reads characteristics. The hash-based (Flicek and Birney, 2009) and Burrows–Wheeler transform (BWT) (Li and Durbin, 2009) methods are the two most popular algorithms utilized as the core algorithm for many alignment software tools. The hash-based method builds either the hash table or input reads to scan the genome reference or in reverse. The software that uses hash table includes mrFAST, SHRIMP (Alkan *et al.*, 2011a,b; Rumble *et al.*, 2009). Another widely used method is the BWT, which creates a suffix array by performing BWT to obtain transformed sequences as a new reference genome for mapping. The BWT method achieves a faster algorithm compared with the hash-based method and is adopted by BOWTIE/BOWTIE2, SOAP2, BWA (Li *et al.*, 2009a,b; Langmead *et al.*, 2009). In addition to these software packages, many more tools can be found in Table 1.

Whole genome assembly follows the step of sequence alignment. The purpose of assembly is to reconstruct the original sequences into large contiguous segments that can be ordered and oriented along each chromosome (Flicek and Birney, 2009). De novo assembly and reference-based assembly are the two main approaches to form longer continuous sequences. De novo assembly involves utilizing computational methods to align overlapping WGS reads for assembling known reads as contigs and order the contigs into the framework of the sequenced genome (Robertson *et al.*, 2010). Referenced-based assembly maps each read to a reference genome sequence and builds a consensus sequence, which is similar but not necessarily identical to the backbone reference (Ng and Kirkness, 2010). Many tools are released online for assembling based on the two algorithms. De novo assemblers include two types: Overlap graphs (Myers, 1995) and de Bruijn graphs (Pevzner *et al.*, 2001). The overlap graph method is used by Canu (Myers *et al.*, 2000) and Arachne (Jaffe *et al.*, 2003), which calculates all the pairwise overlaps between reads and presents the information in the graph. The de Bruijn graph splits reads into k-mers to form the nodes of a network, where k describes the length in bases of these subsequences. Commonly used software based on this method includes Velvet (Zerbino and Birney, 2008), SOAPdenovo (Luo *et al.*, 2012), and ABySS (Simpson *et al.*, 2009). Compared with de novo assemblers, referenced-based assemblers require fewer computational resources but are more challenging in dealing with novel sequences. Examples of referenced-based assemblers include MAQ, SeqMap, and RMAP (Flicek and Birney, 2009; Jiang and Wong, 2008; Smith *et al.*, 2009). We have summarized some frequently used assemblers in Table 2.

Table 1 A list of software for alignment of short reads to the reference genome

Software	Simple description	Resources
MAQ	Build mapping assemblies from short reads generated by the NGS machines	http://maq.sourceforge.net/
ELAND	Hash-based computational alignment program for short oligonucleotides	https://www.illumina.com/
Bowtie/	A short-read aligner that aligns short DNA sequences (reads) to the human	http://bowtiebio.sourceforge.net/index.shtml
Bowtie2	genome at a rate of over 25 million 35-bp reads per hour	http://bowtiebio.sourceforge.net/bowtie2/index.shtml
SHRiMP	Sequence aligner developed with the multitudinous short reads of NGS	http://compbio.cs.toronto.edu/shrimp/
mrFAST	Seed-and-extend alignment tool to map short reads with the Illumina platform	http://mrfast.sourceforge.net/
SOAP	A GPU-based software for aligning short reads with a reference sequence	http://soap.genomics.org.cn/index.html
BWA	A software package that maps low-divergent sequences against a large reference genome	https://github.com/lh3/bwa
SEAL	A suite of distributed applications for aligning short DNA reads, manipulating and analyzing short-read alignments	http://biodoop-seal.sourceforge.net/
BLAST	A suite of programs that align query sequences in a selected target database	https://blast.ncbi.nlm.nih.gov/Blast.cgi

Table 2 Review of most commonly used software in genome assembly

Type	Software	Description	Resources
De novo assembly	Canu	Reconstruct long sequences of genomic DNA from fragmentary data	http://wgs-assembler.sourceforge.net/wiki/index.php?title=Main_Page
	Arachne	Package for assembling genome sequence using paired-end whole-genome shotgun reads	https://github.com/cseed/arachne-pnr
	Velvet	Sequence assembler for very short reads using de Bruijn graphs	https://www.ebi.ac.uk/~zerbino/velvet/
	SOAPdenovo	Short-read assembly method for the human-sized genomes	http://soap.genomics.org.cn/soapdenovo.html
	ABYSS	Assembles the very large data sets produced by sequencing individual human genomes	http://www.bcgsc.ca/platform/bioinfo/software/abyss
Reference-based	SeqMap	Map large amount of oligonucleotide to the genome	http://www-personal.umich.edu/~jianghui/seqmap/
	MAQ	Build mapping assemblies from short reads generated by NGS machines	http://maq.sourceforge.net/
	RMAP	Map reads with or without error probability information and supports paired-end reads	http://rulai.cshl.edu/rmap/
Other	SPAdes Assembly	Standard isolates and single-cell MDA bacteria assembler Unique and stable identifier for the set of sequences that comprise a specific genome assembly	http://cab.spbu.ru/software/spades/ https://www.ncbi.nlm.nih.gov/assembly/
	GAML	Systematic combination of diverse sequencing datasets into a single assembly	http://compbio.fmph.uniba.sk/gaml/

Quality control of sequence reads must be executed during the whole workflow, from sample preparation to alignment and assembly, as well in variant calling and annotation. Many issues can occur when processing genomic data. For example, the reads could be misaligned when performing alignment and assembly, causing systematic error of the device in sequencing and machine cycle (Torri *et al.*, 2012). These problems could lead to the quality score per base and affect the accuracy of variant calling. Unifying the aligned reads into Sequence Alignment/Map or Binary Sequence Alignment/Map format is essential for quality control (Wang *et al.*, 2012). This process could provide us a clean, well sorted, and indexed file as output that could be used in the subsequent analysis. In addition, in some WGS workflows, advanced quality control is also required in recalibrating the base quality scores of sequence reads for variation.

Variant Calling

After the alignment and assembly of short reads, the next step is variant calling, which is a very important step in the WGS pipeline. Variant calling is a conclusion that there is a difference between target sequence and reference at a given position in an individual genome. It is implemented after genome sequence alignment and assembly and the output of variant calling is stored in a standardized generic format called variant call format. These aligned reads differ from genome reference and the variants occurring are probably related to a certain kind of disease or only simple natural mutations without any functional effect in the cell. Based on the characteristics of variants, several different variations are shown in Table 3, which include SNPs/variants, indels, larger structural variants, and CNVs. We give an overview of these four variant calling types and provide the corresponding software packages for the implementation of variant calling.

Table 3 Variant calling tooling for the detection of SNVs, indels, SVs, and CNVs

Calling Type	Software	Simple description	Resources
SNP/Indel	GATK	A collection of command line for the analysis of variant discovery	https://software.broadinstitute.org/gatk/
	SAMtools	A suite of programs for interacting with high-throughput sequencing data	http://www.htslib.org/
	Isaac Variant Caller	Detects SNVs/indels from the aligned sequencing reads of a single diploid sample	https://github.com/sequencing/isaac_variant_caller
	SOAPsnp	Software package for detecting somatic mutation of SNVs by resequencing	http://soap.genomics.org.cn/soapsnp.html
	Dindel	A Bayesian method to call indels from short-read sequence data in individuals	https://github.com/genome/dindel-tgi
SV/CNV	Breakdancer	Detect indels ranging from 10 base pairs to 1 megabase pair via a single conventional approach	http://gmt.genome.wustl.edu/packages/breakdancer/
	iSV	A pipeline that applies multiple tools for detecting structural variants	http://nagasakilab.csmi.org/en/isvp
	Pindel	Detects breakpoints of large deletions, medium sized insertions, inversions	https://github.com/genome/pindel
	SvABA	Detects SVs from short-read sequencing data using genome-wide local assembly	https://github.com/walaj/svaba
	SVMerge	A pipeline detects SVs by integrating calls from existing SV callers	http://svmerge.sourceforge.net/

SNP calling aims to determine in which positions there are polymorphisms or at least one of the bases differs from a reference sequence to describe the genetic relationship between isolates (Nielsen *et al.*, 2011). Accurate calling of SNPs needs high-quality sequencing data, high coverage, and a thorough bioinformatics approach to identify the SNPs in a statistically relevant manner. Indel calling is also a very common form of variant calling that corresponds to the insertion or deletion of base pairs in the sequence of an organism (Hasan *et al.*, 2015). Compared with SNP calling, accurate indel calling is more challenging, because the occurrence rate of indels is almost 8 times lower than SNPs. Various approaches have been applied to perform SNP and indel calling. Bayesian probabilistic procedure is the most frequently used method in the software packages to implement SNP or indel calling. It calculates the score of probability on each genotype and selecting the genotype in the position with highest probability (Li, 2012). The tools include GATK, SOAPsnp, SAMtools, and Isaac Variant Caller (McKenna *et al.*, 2010; Li *et al.*, 2009a,b, 2008; Raczy *et al.*, 2013). In addition, the pattern growth approach is another common method for indel calling by computing the fragments compared to the reference genome from paired-end reads, such as Dindel (Albers *et al.*, 2011).

Moreover, SV/CNV calling is similar to SNP and indel calling. The structural variants have the potential to impact large stretches of sequence, disrupting genes and regulatory elements that are associated with genetic disorders and used as disease markers in clinical diagnosis of diseases. To call large-scale structural variants, which are the source of sequence variation, involving deletion, insertion, and rearrangement of genomic material, it uses discordant fragments and depends on the paired-end reads. By resolving discordant fragments into some breakpoints between fragments through mapping of each end of the paired-end read, the category of a structural variant can be deduced (Fiegler *et al.*, 2006). For example, chromosomal translocations are a type of large-scale SV involving rearrangement of chromosomes. They can disrupt sequences and create new fusion products. Several signature translocations have been identified as mutations that drive the development of disease. The methods that call the relevant variants mainly involve read pair, split read, read depth, and de novo assembly (Alkan *et al.*, 2011a,b). However, there is still a lack of computational framework for SV/CNV calling. Up to now, only a few computational tools have been available, such as Breakdancer, iSV, Pindel, SvABA, and SVMerge (Chen *et al.*, 2009; Mimori *et al.*, 2013; Ye *et al.*, 2009; Wong *et al.*, 2010). Details of the software used for variant calling are listed in Table 3.

Annotation and Analysis

Once the variant calling is completed, the next crucial step is the annotation between the target genome and reference genome to find the potential differences. Genome annotation includes the identification of genome segments of known and probable open reading frames and matching the identified segments to the detected gene sequences from the existing databases (Kwong *et al.*, 2015). It needs to be annotated with biological information. These biological related data range from gene models to gene functions including the Kyoto Encyclopedia of Genes and Genomes (Kanehisa and Goto, 2000) and Gene Ontology (Primmer *et al.*, 2013). A typical genome annotation constitutes a significant effort recorded on the human genome sequences in the reports, which present considerably detailed genome information. The unit record for each genome annotation describes an individual gene and its protein product. Meanwhile, simple evidence of the assigned function for the variants may also be stored in the file, for example, boundary of domains and functionally characterized homolog, but the details of the information need further exploration. The process of annotation conceptually contains two parts, namely the computational part and the annotation part. The computational part consists of the data from genomes or specific transcriptomes that are used in parallel to create initial gene and transcript information. The annotation part is used to synthesize the information into a gene annotation by a set of rules in an annotation pipeline. Usually, the success of genome annotation strongly relies on the quality of genome assembly so that it will produce satisfying results in terms of near-complete genomes broken by small gaps.

The purpose of genome analysis is to explore the effect of genomic variants on wild-type gene function and further on overall individual health. The progress of WGS has been yielding an increasing number of genetic variants. Identification of the disease-associated variants and seeking their specific types, locations, potential effects, and functions is complicated and challenging because of issues such as complex genomic regions, inaccurate variant calling, detection of the phase of the locus, etc. The causation between genomic variants and disease association is the key point during the process of genomic annotation and analysis, which could help us acquire explicit understanding on variation effects of individuals (Albert and Kruglyak, 2015). Many excellent resources and programmable workflows are usable for the annotation and analysis of identified variants that differ by type. Almost all the tools can process SNPs and indels, but for SV annotations, only a few tools are available like ANNOVAR (Wang *et al.*, 2010) and VAT (Habegger *et al.*, 2012). Also, these tools could achieve distinct functions such as reference database annotation, evolutionary information, prediction of identified variant effect, allele frequency, chromosomal position regarding to the nearby site of interest (e.g., gene, segmental duplication, splice site, regulatory region, etc.) (Bromberg, 2013). All these findings or results are the outcomes of individual variants that can be used for the diagnosis of disease. Some common tools for the execution of annotation and analysis are shown in Table 4.

The frameworks above present the steps and provide available tools for the implementation in each process. Such processes sequentially linked together constitute the complete computational WGS workflow. A number of platforms have been developed for the processing of genome sequencing analysis that integrate and manage pipelines. The most widely used WGS platform may be Illumina, which achieves DNA colony amplification by bridge PCR, sequencing-by-synthesis, and fluorescence imaging (Lunter and Goodson, 2011). The types of Illumina instruments vary a lot in terms of the function and cost, including MiSeq, NextSeq, HiSeq, HiSeq X Ten, etc. The Ion Torrent platform, a competitor to Illumina, is similar to cyclic array platforms in amplifying DNA colonies on beads that are immobilized within wells on a patterned surface. This system utilizes a novel and nonoptical detection method, measuring the release of a hydrogen ion (Merriman *et al.*, 2012). Pacific Biosciences is another platform that offers comprehensive solutions and advanced applications of WGS for complete gene discovery. Though, the cost is more expensive than alternatives, the combination of long reads and minimal GC bias for large-scale WGS by Pacific Biosciences allows access to a substantially larger portion of human genetic variation, an intrinsic advantage over short-read sequencing technology (Carneiro *et al.*, 2012). Another noteworthy platform is Oxford Nanopore, which uses low quantities of input nucleotides and long reads without manipulation (Mikheyev and Tin, 2014). Besides, there are many other companies and communities that are keen on exploiting novel and advanced WGS technologies including Galaxy, LONI, GATK, Taverna, etc. (Giardine *et al.* 2005; Rex *et al.*, 2003; McKenna *et al.*, 2010; Oinn *et al.*, 2004), so we are optimistic for the prospects of WGS platform development in the future.

Clinical Workflow and Application

The application of WGS shows a broad range across different fields, including agriculture, food, public health, even in space for a variety of settings and reasons. In this article, we only discuss its clinical applications, which are closely related to human health and life. The clinical application of WGS represents the elucidation of the genomic determinants of humans' heritable makeup. In fact, many genome projects have been released concentrating on the use of WGS for diagnosing those with rare and common diseases, cancer, etc. We anticipate that this description will continue to advance our understanding of pathophysiology with WGS and realize its value in discovering genes and variants for underlying disease and improving public health.

Current clinical applications mainly consist of Mendelian diseases, complex diseases, and cancer (Wu *et al.*, 2016). The diagnosis of Mendelian disease is the most common application of genome sequencing of individual patients that has been successfully applied in the identification of causal mutations (Lupski *et al.*, 2010; Roach *et al.*, 2010). The largest collection of Mendelian disease contains 7000 distinct diseases that are characterized based on the OMIM database (Hamosh *et al.*, 2002).

Table 4 A list of available software in genome annotation

Software	Simple description	Sources
ANNOVAR	Utilizes up-to-date information to annotate genetic variants detected from diverse genomes	http://annovar.openbioinformatics.org/en/latest/
VAT	A computational framework to functionally annotate variants in personal genomes	http://vat.gersteinlab.org/
VARIANT	Provides annotation of variants from NGS based on several different databases and repositories	http://variant.bioinfo.cipf.es/
VAAST	Identifies damaged genes and their disease-causing variants in personal genome sequences	http://www.yandell-lab.org/software/vaast.html
snpEFF	Annotates and predicts the effects of SNP, indel, and MNP variants in genomic sequences	http://snpeff.sourceforge.net/
VariBench	A benchmark database for testing and training methods for variation effect prediction	http://structure.bmc.lu.se/VariBench/
PolyPhen/ PolyPhen-2	Algorithms that predict possible impact of an AAS on the structure and function of human protein based on sequence, phylogenetics, and structure	http://genetics.bwh.harvard.edu/pph2/
SeattleSeq	Annotate novel and known SNVs and small indels with biological functions, protein positions, etc	http://snp.gs.washington.edu/SeattleSeqAnnotation150/

Almost half of them are caused by unknown genetic elements. The diagnosis of Mendelian disease by WGS workflow includes the combination of gene information, variant function prediction, variant frequency, and evolutionary conservation. The rationale underneath is the assumption that the variants related to the Mendelian diseases that change the protein function on corresponding genes tend to be rare. Common or complex diseases are another type of clinical application affected by more than one variant. Genome-wide association studies explore complex disease due to the variants that contribute to disease susceptibility with modest effect size. However, genome-wide association only genotypes common variants. The technique of WGS makes it possible to annotate all variants, including rare and common variants, and guarantee the sequencing of real functional genes. The identification of cancer, regarded as an important type of complex disease, has been in great demand in recent years. Much attention has been paid using whole exome sequencing to detect multiple types of cancers such as breast cancer, gastric cancer, and prostate cancer (Barbieri *et al.*, 2012; Wang *et al.*, 2011; Thompson *et al.*, 2012). Although certain types of cancer detection have obtained immense success, it still exposes the issue that whole exome sequencing only focuses on the protein coding region and ignores the noncoding region, which blocks the wider and deeper study of cancer. With increasing development of sequencing technology, WGS is solving the issue of identifying noncoding regions that are frequently mutated across cancer types, which creates opportunities for personalized medicine in the future (Tsai *et al.*, 2016).

We provide the MedSeq Project, the first randomized clinical trial that integrating WGS into clinical medicine, as an example to draw the outline of WGS clinical workflow for healthy individuals and individuals with disease (Vassy *et al.*, 2014). The holistic view of clinical WGS workflow is depicted in Fig. 2; this mainly consists of five components, namely patients, hospitals, lab experiments, reports and feedback, and solutions.

Limitations and Future Development

With the rapid progress of genome sequencing techniques and powerful tools and platforms, there are still limitations that obstruct the widespread use of WGS. The first challenge is that WGS may not detect all of the variations in a genome. For example, variations that cause DNA repetitions or rearrangements can hardly be detected by WGS, which means you may have variants that could deceive you to a certain genetic condition that escapes detection. Also, occasionally a portion of a gene may not be readable by WGS and the variants could be missed. The second is the interpretation of genetic variants in genes, especially related to human disease. The lack of a test and comparison in clinical research is still an immense issue, although many relevant studies are frequently published on the meaning of biological variants (Krier *et al.*, 2016). The development of a standardized evaluation of

Fig. 2 The outline of clinical workflow of whole genome sequencing.

WGS pipelines for validation in clinics is of great significance to public health. The third remains the further improvement of methods and techniques for pipeline construction. WGS has extensively detected SNVs and indels, but for the identification of SVs and CNVs as well as genomic rearrangements, it remains in its infancy. Therefore, more innovative methods and advanced analysis techniques (such as deep WGS), which have not yet been applied as part of common workflow in most of the existing research and practical projects, need to be further explored.

Despite these challenges, we are still confident and looking forward to the bright future of WGS. We can expect continuous improvement on the steps of the WGS pipeline by sequencing technology and computational methods. New library construction enables sequencing by producing libraries with longer and more precise sizes and generating longer reads with less error rate. More efficient algorithms and stronger computation power could further reduce computing time and cost for genome sequencing, which will make WGS become routine in both genetics research and clinical application. After the enhancement in techniques and methods, there is no doubt that user-friendly and advanced workflows are the key to facilitate more widespread use of WGS. The unification of the pipeline with WGS in a shared and specified language, as well as common tools, will bring much convenience with the expanding community of users and producers of genomic data. This transition makes it possible that even small research teams or individuals with limited resources will be able to develop genomic studies and strengthen the use of WGS techniques in biology and related fields. As more multidimensional data and more-populated databases are generated (e.g., genetic pathways, functions, biomedical information) through research institutions and hospital networks, abundant variants will be detected, which will bring us a great chance for new discoveries to figure out the relation between variations and effects in certain diseases. In addition, the methods for storing and sharing WGS data seamlessly, construction of databases containing millions of individuals with diverse health networks using WGS, as well as the integration of genotypic and phenotypic information are also critical steps for the prosperity of future directions in WGS development.

Introduction

Metagenomic analysis is commonly used to investigate complex microbial communities sampled directly from the environment, without culturing or isolating a single organism. Microbes have important roles to play in various ecosystems, however, many remain to be characterized in detail. The term metagenomics was coined in 1998 ([Handelsman et al., 1998](#)); it helps to understand various aspects of a sample, and allows one to characterize the microbes in the given environmental sample. It helps identify the species present in the community and also provides insights about the metabolic activities and functional roles of the microbes in the environmental sample ([Langille et al., 2013](#)).

Current approaches allow one to understand the complex properties of the microbiota, their dynamics and function in the natural system. Various metagenomic approaches answer fundamental questions such as which organisms are present (Taxonomic diversity), and what roles they play (Functional metagenomics) ([Vieites et al., 2008](#)). The amplification of specific targeted genes such as (V1-V9) of 16S rRNA, 18S rRNA, ribosomal ITS, NifH, among others, by PCR before sequencing permit diversity analysis ([Morgan and Huttenhower, 2012](#)). The relative abundance of the most abundant microorganisms of a particular group is not necessarily associated with the importance of that group in the functioning of the community. The most abundant organisms may not always play the most critical role in a community, while organisms constituting only 0.1% of the community (e.g., nitrogen fixers) can have very important functions ([Dinsdale et al., 2008](#)).

Types of Metagenomics Studies

The two most commonly used methods of pathogen identification for high throughput data are (1) Amplicon based method which includes 16S ribosomal RNA for bacteria, internal transcribed spacer (ITS) and 18S region for fungi and eukaryotes, respectively, and (2) whole metagenomic shotgun sequencing.

Shotgun Metagenomics

Shotgun metagenomic analysis has the ability to identify the majority of the organisms (culturable and unculturable bacteria) in the environmental sample. A community biodiversity profile is created, which is further associated with functional composition analysis of organism lineages (i.e., genera or taxa) ([Tringe et al., 2005](#)). Shotgun metagenomic studies can be divided into two types: (1) Sequence-based screens, which describe the microbial diversity and genomes of a particular environmental sample, and (2) Functional screens, which identify the functional gene products, but do not determine from what species the genetic material originated ([Madhavan et al., 2017](#)). Before initiating a whole metagenomic study, an understanding of the potential microbial diversity and the relative abundance of species in the environmental sample is very important. For example, the metagenome of soil samples will consist of a more complex microbial community, than human skin. Hence, for proper coverage, more data must be generated in case of soil than for human skin. A higher sequencing depth also allows the detection of rare taxa ([Sharpton, 2014](#)). This makes shotgun metagenomic sequencing much more expensive than 16S sequencing, in order to achieve the coverage and depth needed for species identification ([Quail et al., 2012](#)).

Amplicon Based 16S

16S sequencing is a widely used technique that relies on the variable regions (V1-V9) of the bacterial 16S rRNA gene to make community-wide taxonomic assignments ([Chakravorty et al., 2007](#)). It is also used for microbial diversity analysis and has been used for various environmental samples, such as soil ([Chong et al., 2012](#)) and human gut ([Dethlefsen et al., 2008](#)), among others. Some degree of divergence is allowed during the sequence similarity assessment stage of the analysis; typically, nearly identical sequences (> 97%) are clustered into Operational Taxonomical Units (OTU) ([Morgan and Huttenhower, 2012](#)). The limitation of this method is that, if any two organisms have the same 16S rRNA gene sequence, they may be classified as the same species in a 16S analysis, even if they are from different species. Because 16S analysis is based on the 16S rRNA gene, with OTUs defined as taxa, it is generally not possible to distinguish strains, nor, in some cases, closely related species. For example, *Escherichia coli* O157: H7 and *E. coli* K-12 cannot be differentiated based on 16S analysis ([Weinstock, 2012](#)), nor can *Shigella flexneri* be distinguished from *E. coli* ([Hilton et al., 2016](#)). The OTUs are analyzed at each taxonomic level, but are less precise at the species level ([Ranjan et al., 2016](#)).

Amplicon Based 18S/ITS

The 18S rRNA is one of the basic components of fungal cells and comprises both conserved and hypervariable regions. The internal transcribed spacer region, ITS, is located between the 18S and 5.8S rRNA genes and has a high degree of sequence variation. The 18S rRNA is mainly used for high resolution taxonomic studies of fungi, while the ITS region is widely used for analysing fungal diversity in environmental samples (Bromberg *et al.*, 2015). Taxonomic studies of fungi are often based on the nuclear ribosomal gene cluster, which includes the 18S or small subunit (SSU), 5.8S subunit, and 28S or large subunit (LSU) rRNA genes. ITS1 and ITS2 have been found to be the most suitable markers for fungal phylogenetic analysis due to their variable sequences, conserved primers and multicopy nature (Cuadros-Orellana *et al.*, 2013). Various pipelines, such as QIIME (Caporaso *et al.*, 2010), MG-RAST (Glass *et al.*, 2010) and Mothur (Schloss *et al.*, 2009) are used to perform taxonomic and functional analysis (Table 1). In QIIME, the UNITE database is used as it includes fungal rDNA ITS sequences (Kõljalg *et al.*, 2005). In addition to rRNA genes, other amplicon-based studies are performed in order to focus on specific functions such as nitrogen fixation activity, and diversity analysis of nitrogenase reductase (nifH) genes (Igai *et al.*, 2016). Arbuscular mycorrhizal fungi have been found in a symbiotic relation with the roots of plants (Smith and Read, 2008) based on analyses of the fungal SSU rRNA gene (Vasar *et al.*, 2017).

Metatranscriptomics and Metaproteomics

RNA-Seq analysis of microbial communities in a complex ecosystem is known as Metatranscriptomics (Zhang *et al.*, 2017). Co-expression of gene clusters and transcript abundance, followed by functional annotation, can be studied in environmental samples (Oyserman *et al.*, 2016). The quantitation of mRNA and pathway expression can be carried out using metatranscriptomics. The challenge associated with metatranscriptomic approaches is to get high quality RNA from environmental samples; given this, it is an efficient approach to elucidate gene expression, and to discover novel genes in the microbial community (Frias-Lopez *et al.*, 2008; Tartar *et al.*, 2009).

The study of the proteome expressed in the microbial community is known as Metaproteomics. This has been used to investigate microbial activities along with complex metabolic pathways in soil ecosystems (Zampieri *et al.*, 2016). Community metaproteomics are emerging as complementary approaches to metagenomics and can provide large-scale characterization of proteins in the microbiota, such as in the human gut (Petriz and Franco, 2017). Metagenomics, along with metatranscriptomics and metaproteomics, provide insights into functional dynamics, prediction of the in situ microbial responses/activities, and the production capabilities of microbial communities (Simon and Daniel, 2011).

Analysis of the metagenome

In this section, we discuss the various analysis pipelines for the types of metagenomics studies shown in Fig. 1 (credit to Oulas *et al.*, 2015).

Shotgun Metagenomic Analysis

Metagenomics studies are carried out to investigate both known and unknown species, both culturable and unculturable, in the environmental sample studied. A *de novo* assembly of shorter reads may be carried out to obtain genomic contigs, followed by scaffolding, which is often performed to get a more compact and concise view of the sequenced environmental samples. Achieving full assemblies of the complete genomes present in the community is difficult, and is rarely possible except in simple communities, or with very deep sequencing (Tyson *et al.*, 2004; Venter *et al.*, 2004). In metagenomic studies, insight into the metabolic functions active in the environmental sample can be obtained based on the complete sequences of protein coding genes, as well as from the full operons present in the sequenced genomes (Oulas *et al.*, 2015).

Pre-processing of sequence reads for metagenomics

The raw reads generated from the next generation sequencing platform are subjected to adapter trimming, quality filtration, and de-replication. If the metagenomic sample is isolated from a host organism, then host contamination is typically removed by aligning to the reference genome of the host organism using bowtie2 or other short-read mapper (Oulas *et al.*, 2015).

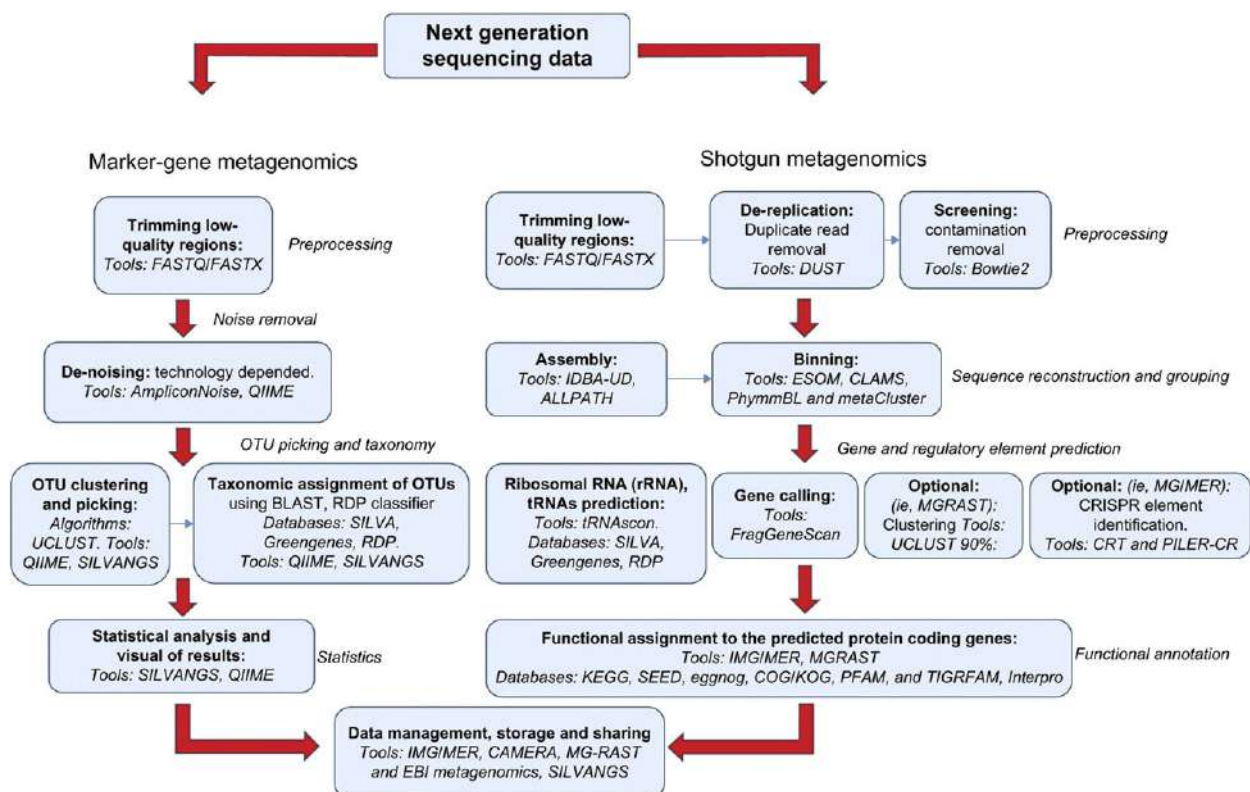

Fig. 1 The overview of the whole metagenomics and 16S analysis (marker-gene metagenomics). Reproduced from Oulas, A., Pavloudi, C., Polymenakou, P., *et al.*, 2015. Metagenomics: Tools and insights for analyzing next-generation sequencing data derived from biodiversity studies. *Bioinformatics and Biology insights* 9, 75.

Fig. 2 Representation of Krona. Note: The 16S metagenome sample was analyzed using QIIME and displayed using Krona. The Taxonomy nodes are arranged from the top of the hierarchy at the center and progressing outward. The chart is zoomed to place the domain "Proteobacteria" at the root followed by the taxon.

De novo assembly

Assembly is computationally expensive and requires sophisticated algorithms, such as those based on de Bruijn graphs. Tools that are specifically designed for metagenomic applications are mainly built on de Bruijn graph algorithms. A few common metagenomics assembly tools include CLC workbench, Meta-Ray, MetaVelvet-SL, MetaVelvet, Meta-IDBA SOAP, and metaSPAdes (Nurk *et al.*, 2017; Zerbino and Birney, 2008; Luo *et al.*, 2012). A reference-guided assembly may be carried out when an appropriate reference genome is available (Nagarajan *et al.*, 2010).

Binning

The process of clustering reads or contigs into highly similar groups, and assigning the groups to specific species, subspecies or genera, is called binning. Two types of algorithms are available: (1) Composition-based binning and (2) Similarity-based binning. Certain binning tools deploy hybrid approaches which implement both kinds of algorithms (Oulas *et al.*, 2015). Composition-based binning groups, in a supervised or semi-supervised manner, the DNA fragments with similar composition. Similarity-based methods align the DNA fragments to NR database or reference sequences (Leung *et al.*, 2011).

Annotation

Prediction of CDS (coding DNA sequences), followed by functional assignment is carried out using similarity-based searches of query sequences against databases containing known functional and/or taxonomic information. The taxonomic information can be displayed using Krona, which displays hierarchical data as an interactive multilayered pie chart (Ondov *et al.*, 2011). The

predicted genes are annotated to identify homologous genes (Wheeler *et al.*, 2007), Gene ontology terms (Ashburner *et al.*, 2000), KEGG pathways (Kanehisa *et al.*, 2009), protein families using Pfam (Bateman *et al.*, 2004) or TIGRFams (Haft *et al.*, 2003), clusters of orthologous genes (COGs/KOGs) (Tatusov *et al.*, 2003) or orthologous families (EggNOG, Jensen *et al.*, 2007), and functional motifs using InterPro (Hunter *et al.*, 2008). Sequence similarity-based algorithms such as BLAST require high-performance computer clusters. Some tools, such as Kaiju (Menzel *et al.*, 2016), assign taxonomy using a reference database, and also integrate the Krona tool for visualization as shown in Fig. 2, and COGNIZER (Bose *et al.*, 2015) can be used for functional annotation, which employs a new approach of search strategy that helps in reducing the computational requirements.

Amplicon Based Metagenomic Analysis

The study of microbial diversity in natural environments can be carried out by targeting specific genes. For diversity analysis of bacteria and archaea community, the 16S rRNA gene is commonly used as it contains one or more variable regions (Woese, 1987). For fungi and eukaryotes, the internal transcribed spacer (ITS) and 18S rRNA gene are used, respectively. Commonly used tools for 16S rRNA analysis are QIIME (Quantitative Insights Into Microbial Ecology) (Caporaso *et al.*, 2010), Mothur (Schloss *et al.*, 2009), SILVAngs (Quast *et al.*, 2013), RDPipeline (Ribosomal Database Project Pipeline) (Cole *et al.*, 2013), MEGAN (Huson *et al.*, 2007), and MG-RAST (Metagenomics - Rapid Annotation using Subsystems Technology) (Meyer *et al.*, 2008) as listed in Table 1. Despite the availability of so many tools and databases for 16S rRNA analysis, QIIME is considered to be the “gold standard” (Nilakanta *et al.*, 2014). Widely used rRNA databases include Greengenes (16S) (DeSantis *et al.*, 2006), Ribosomal Database Project (16S) (Cole *et al.*, 2006, 2008; Maidak *et al.*, 1996), Silva (16S & 18S) (Pruesse *et al.*, 2007; Quast *et al.*, 2012) and UNITE (ITS) (Köljalg *et al.*, 2013).

Pre-processing of reads for amplicon analysis

The raw files generated from the next generation sequencing platform are subjected to demultiplexing, adapter trimming and quality filtration (Plummer *et al.*, 2015). PCR product chimera detection and removal is carried out using UCHIME algorithm (Sinclair *et al.*, 2015).

OTU picking and taxonomic assignment

OTU picking groups similar sequences by clustering or a similarity-based method. OTU picking in the most popular tool QIIME is performed using the UCLUST program. The UCLUST program uses the USEARCH algorithm to assign the sequences to clusters (Edgar, 2010). Each OTU represents a cluster of sequences with similarity greater than a threshold, typically 97%–98%, which is then assigned to a corresponding taxonomic group. There are various OTU picking strategies: (1) *De novo*, wherein the reads are clustered without reference to known sequences. (2) Closed-reference, in which the reads are clustered based on the alignment to a reference database or (3) Open reference method, which clusters reads against a reference database and also clusters unaligned reads using a *de novo* approach. All these methods are incorporated in QIIME (Oulas *et al.*, 2015). The taxonomical diversity can be represented as an abundance histogram. Further analysis can be done with decomposition methods such as Principal Coordinate Analysis (PCoA) or Canonical Correlation Analysis (Johnson and Wichern, 2014). The taxonomical diversity can be represented using Krona, Fig. 2 shows one layer of a Krona plot at the Proteobacteria level.

Statistical Analysis

The taxonomic tree in Newick format can be obtained from QIIME, and can be visualised using any tree display tool, for instance FigTree (FigTree is available at: <http://tree.bio.ed.ac.uk/software/figtree/>). Alpha diversity measures variability within a single population, which measures richness, dominance, and evenness. Other diversity metrics include, for example, Phylogenetic Diversity (PD), Chao (1984) Shannon entropy (Gorelick, 2006), among others. Rarefaction analysis is used to assess the coverage of the microbial community in the sample. Rarefaction curves plot the sample size versus the estimated number of genera (Jaenicke *et al.*, 2011). Beta diversity is the diversity across many populations or samples, which is calculated using various matrices, such as unweighted and weighted UniFrac (Lozupone *et al.*, 2006) and PCoA (Principal Coordinate Analysis). It includes absolute or relative overlap between samples to estimate the taxa shared among them. Calculation of alpha and beta diversity is supported by QIIME.

Metagenomics Phylogenetic Analysis

The taxonomic methods can provide information at specific taxonomic hierarchy, such as phylum, class, order, family, genus and species (Darling *et al.*, 2014), whereas phylogenetic approaches help in identifying species and novel lineages at taxonomic levels (Darling *et al.*, 2014). Different tools used for the phylogenetic analysis of metagenomes are AmphoraNet (Kerepesi *et al.*, 2014), TIPP (taxonomic identification and phylogenetic profiling) (Nguyen *et al.*, 2014), and Phylosift (Darling *et al.*, 2014), among others.

The PhyloSift database includes a set of “elite” gene families of Bacteria and Archaea, and also includes additional four sets of gene families *i.e.* 16S and 18S ribosomal RNA genes, mitochondrial gene families, eukaryote-specific gene families, and viral gene families. The metagenome reads are searched against the defined set of gene database to predict taxonomy. The query sequences are aligned with the reference genes in the database. The sequences are assigned on a phylogenetic tree using Pplacer and taxonomic assignment is carried out (Darling *et al.*, 2014). This approach is based on statistical phylogenetic models *i.e.* Bayesian hypothesis testing and OTU-free analyses (Darling *et al.*, 2014). The AmphoraNet webserver uses the AMPHORA2 workflow for phylogenetic diversity analyses of metagenomic data (Wu and Eisen, 2008), where query sequences are aligned to bacterial and archaeal protein

coding marker genes. Alignment to marker genes is carried out using a hidden Markov model trained on a reference database of fully sequenced bacterial genomes (Wu M and Eisen J 2008). The metagenomic reads are used as an input in AmphoraNet to search, align and mask the data against the HMM trained model, followed by phylogenetic analysis using RaxML on the masked metagenomics sequence (Kembel *et al.*, 2011). Phylogenetic analysis is one of the critical steps in analysing metagenomics data, with applications in improved classification of sequences using phylogenetic methods, functional prediction of genes, and improved identification of OTUs, among others (Darling *et al.*, 2014).

Functional analysis

To predict the functional composition of microbial communities from the 16S profile, PICRUSt (Langille *et al.*, 2013) can be used. It uses an extended ancestral-state reconstruction algorithm, which predicts the gene families and then combines gene families to estimate the composite metagenome. The annotation of the predicted gene family counts are obtained from orthologous groups of gene families, KOGs, COGs, NOGs, or Pfam families (Langille *et al.*, 2013).

Metatranscriptomics/Metaproteomics Analysis

Metatranscriptomics allows the characterization and functionality analysis of the microbiome under study. It provides RNASeq-based measures of gene expression and regulation in the microbial community. The analysis used for metatranscriptomics is the same as in metagenomics (Simon and Daniel, 2011). The analysis can be carried in two approaches (1) *de novo* and (2) reference based. There are many *de novo* assembly tools, as listed in Table 1. Read alignment is carried out using standard short-read mapping tools such as bowtie2, or BWA. To study differentially expressed genes, statistical tools are used such as DESeq2 and edgeR (Bikel *et al.*, 2015).

Metaproteomics is the study of the total proteome expressed in the microbial community. This can be used to study metabolic pathways, and to identify enzymes present in unculturable microbes and communities (Simon and Daniel, 2011; Madhavan *et al.*, 2017).

The metaproteomic approach has four steps: sample collection, protein extraction, purification and fractionation; mass spectrometric (MS) analysis; and finally protein identification and further bioinformatics analyses. Raw data (SDS PAGE, MALDI-TOF-TOF, MS (LC-ESI-MS/MS)) are interpreted using software packages such as Mascot, SEQUEST and *de novo* analysis software such as PEAKS to identify peptides and proteins. There are two approaches for this: direct mass spectra based or *de novo* peptide sequence based, each of which is followed by a quantitative step, along with visualization of the complex functional information (Wang *et al.*, 2014a,b).

Application

Metagenomics has a wide range of applications from clinical to environmental samples, from food safety to industrial waste, and also has the ability to identify pathogens. For example: Lettuce has an immense number of viruses on it, which can infect various hosts, such as humans and animals. Metagenomics can detect human and animal viruses on lettuce samples, which can identify viral contamination of the green leaves in the field (Aw *et al.*, 2016). These approaches help to determine the source of microbial and viral contamination, and can be used to identify the critical steps where such contamination occurs, and to implement improved processes to ensure food quality and safety (Doyle *et al.*, 2017).

Metagenomics provides information about the diversity of organisms in environmental samples and has provided insights in industrial research. Functional metagenomics has been used for identification of several biocatalysts, which are available in the market, for example: laccases, esterases and nitrile hydratase (Fernández-Arrojo *et al.*, 2010). Novel cellulases with improved enzymatic characteristics have been identified; cellulose is an important component of plant biomass, and is the most abundant polymer in nature (Fang *et al.*, 2010). The use of metagenomics, metatranscriptomics and metaproteomics approaches enhance enzyme discovery and can be used to efficiently screen for highly active enzymes (Madhavan *et al.*, 2017). Recent studies (Devarapalli and Kumavath, 2015), have stated that metagenomics can be used as a bioremediation tool; in comparison with other approaches of bioremediation, metagenomics gave better degrading ratios. Metagenomics study help in identifying different widespread microorganism and their respective functions in polluted environment; these microorganisms are the best tools in nature to degrade toxic pollutants (Devarapalli and Kumavath, 2015).

Metagenomics has been used in clinical diagnostics. For example, metagenomic approaches have been used for identifying novel noninvasive diagnostic bacterial biomarkers from fecal samples, for diagnosis of colorectal cancer (Liang *et al.*, 2017). The 16S rRNA is a powerful approach for developing diagnostics, for example, for detecting bacterial bloodstream infections (bBSI) (Decuyper *et al.*, 2016). Viral metagenomics has the power to identify the root cause of novel epidemic diseases (Mokili *et al.*, 2012). Metagenomics is also used in medical or forensic investigations, and to solve challenges in the field of medicine, agriculture and ecology. Major applications of metaproteomics have included investigation of acid mine drainage biofilms, activated sludge, soil, human gut microbiota, and other environmental samples (Wilmes *et al.*, 2015).

Discussion and Future Direction

Microbes survive in a vast range of environmental conditions and are found throughout nature. Most of them are unculturable, so they are difficult to identify by traditional methods. Metagenomics is a molecular tool used to analyse DNA acquired from

environmental samples, in order to study the community of microorganisms present, without the necessity of obtaining pure cultures. It is most often applied to bacteria, but can also be applied to archaea, viruses, and eukaryotes (Morgan and Huttenhower, 2012). Metagenomics provides a platform for studying the physiology and genetics of uncultured organisms. It can refine the approach of genomics and accelerates the rate of gene discovery. Metagenomics has a future in diagnostics, in which it could be applied to any specimen (for example plant, human, and *etc.*) to detect pathogens, such as bacteria, viruses, fungi, and parasites. Metagenomics in diagnostics has various challenges as there is wide range of abundance of different taxa in particular samples (Pallen, 2014). Identifying the causative agent of a new epidemic is one of the most important steps for effective response to disease outbreaks. Traditionally, virus discovery required propagation of the virus in cell culture, which has resulted in limited knowledge of viruses. Study of viral metagenomes suggests that the field of virology has explored much less than 1% of viral taxonomic diversity (Mokili *et al.*, 2012). The study of gene expression and protein production in the microbial community complement metagenomic analysis. Metatranscriptomics and metaproteomics approaches provide powerful tools for understanding the functional dynamics of microbial communities (Simon and Daniel, 2011).

Metaproteomics studies have not been used to their full potential in comparison to metagenomics and metatranscriptomics. Metaproteomics studies can provide deep insights into diverse biological questions regarding health and disease. Emerging technologies should improve the ability of metaproteomic approaches to handle the wide dynamic ranges of different metaproteomic samples, and also help in understanding protein modification (Wilmes *et al.*, 2015). Metaproteomics has emerged as complementary approach to metagenomics, which aims at the characterization of proteins from environmental microbiota (Petriz and Franco, 2017).

Biographical Sketch

Arpita Ghosh is a Manager of Bioinformatics at Eurofins Genomics India Pvt Ltd/ Eurofins Clinical Genetics India Pvt. Ltd. She is also a PhD student at Perdana University, Malaysia. She has a rich research experience of more than seven years in various fields of genomics and clinical genetics data analysis using Next Generation Sequencing technology. She has published more than 15 international publications in different areas of genomics and clinical genetics. She has been working on cutting edge applications of genomics like amplicon based metagenomics (16S, ITS), whole metagenome, WGS, RNASeq, small RNA, GBS and Tilling, among others. Her current research is on virus metagenomics and to identify novel genes from viral genomes. Her primary research interest is in the field of genomics, application heat of which can be felt invarious fields such as molecular diagnostics and the study of the environment.

Aditya Mehta has more than five years of Industrial research experience in various fields of applied genomics and translational genomics data analysis using various next generation sequencing platforms. He has worked on large scale data analysis projects like RNASeq, whole genome, Metagenomics and 16S/18S analysis using high throughput sequencing data. He has extensive experience in analysing metagenomics and 16S rRNA data generated on Illumina platform. He has carried out large scale data analysis of various metagenomics samples like soil, water and the human gut and identified microbial diversity, their relative abundance in sample and also deciphering the gene functions. He has in depth knowledge of various metagenomics tools, software and databases that are widely used for microbial data analysis and taxonomical identification from experimental sample. He has designed new strategic approaches and workflow steps for microbial data analysis, including further downstream analysis.

Dr. Mohammad Asif Khan is currently appointed as the Director of the Perdana University Center for Bioinformatics (PU-CBi), Malaysia, and a Visiting Scientist for the Department of Pharmacology and Molecular Sciences, Johns Hopkins University School of Medicine (JHUSOM), USA. His research interests are in the area of biological data warehousing and applications of bioinformatics to the study of immune responses, vaccines, venom toxins, drug design, and disease biomarkers. He has contributed in the development of several novel bioinformatics methodologies, tools, and specialized databases, and currently has three patent applications granted.

Integrative Analysis of Multi-Omics Data

Introduction

Biomolecular interactions among elementary units of a living system such as DNA, RNA, proteins, lipids and also small molecule metabolites make up the different organisational levels of the cellular networks such as microRNA (miRNA)-target interactions (MTIs), protein-protein interactions (PPIs), transcription factor (TF)-target gene interactions and protein-chemical compound (small molecule) interactions (PCIs); such interactions underlie the complexity and functioning of all biological processes. The key step in biology is to understand how these different components come together and how they interact with each other and define the emergent behaviour of the living systems.

The quest to uncover the mechanisms underlying complex biological processes and the proliferation of various high-throughput “omics” experiments have resulted in an unprecedented surge in the diversity, volume and complexity of *genomics*, *transcriptomics*, *proteomics* and *metabolomics* data among others. *Genomics* data provide an overview of the complete set of genetic instructions provided by the DNA including the variants within; *transcriptomics* data provide insights into gene expression patterns; *proteomics* data examine the cellular dynamics of proteins and their interactions and *metabolomics* can be used to determine the differences between the levels of thousands of molecules between healthy and diseased conditions. The availability of such data have, therefore, opened up a myriad of opportunities for new biological discoveries.

Typically, omics datasets are analysed separately using varied statistical and computational methods and approaches. The analysis of PPI Networks (PPIN) (Huttlin *et al.*, 2017, 2015; Rolland *et al.*, 2014), genetic interactions (Boucher and Jenna, 2013), gene co-expression networks (van Dam *et al.*, 2017; Serin *et al.*, 2016) and metabolic interaction networks (Krumisiek *et al.*, 2016), among others, have provided valuable biological insights into the set-up of the cellular machinery. However, the single-datatype analyses only offer glimpses into one of the many layers that govern the cellular machinery; they do not take into account the relationships and interactions between different biological entities across different organisational layers. Therefore, combining different types of omics data into a single analytical framework provides an opportunity to simultaneously examine the multiple cellular organisational layers, understand the complex interactions between them and gain deeper insights into how their combined influence determines the behaviour of the biological systems (Yan *et al.*, 2017; Civelek and Lusi, 2014; Zhu *et al.*, 2012). Such integration can also facilitate a better understanding of how living systems adapt and modulate their responses to different environments and also help reduce the noise and false positives emanating from single source data sets.

A systems biology-based multi-omics data analysis approach seeks to integrate disparate omics data with bioinformatics tools for data manipulation and pattern discovery into an integrative data analysis pipeline to derive conceptual systems level models of genes and biological processes. Such integrative models can empower the researchers to predict complex traits, understand genotype-phenotype correlations, gain the knowledge of biological pathways involved in different traits and diseases and therefore, help prioritise biologically and therapeutically relevant genes and proteins (Krumisiek *et al.*, 2016; Koczynski *et al.*, 2017; Sun and Hu, 2016; van Kampen and Moerland, 2016; Fukushima *et al.*, 2014; Berger *et al.*, 2013) (Fig. 1).

In this review we will discuss the different types of omics data and how they have been individually analysed. We will then discuss how the analysis of large data sets from different omics platforms has been performed using different approaches such as network modelling and pathway analysis. We finally discuss the future trends in the field.

High Throughput Omics Datatypes and Methodologies

Genomics

Every biological function has its basis in the genetic information of an organism. A better understanding of the genetic determinants of cellular processes including diseases is therefore necessary to gain the knowledge of biological systems, unravel disease mechanisms and develop effective therapeutic approaches. To achieve this, researchers have for long sought to determine the sequences of individual genes of interest. With the advent of high-throughput DNA sequencing technologies, it became possible to sequence the whole genome that is the complete set of DNA within a cell or an organism. Thus, the focus has shifted from investigating individual genes to mapping, annotation and characterisation of the whole genome, a study called *genomics*. The availability and analysis of whole genome sequence data have contributed immensely to the understanding and evolution of gene function in different species and disease mechanisms. Comparative genomics refers to the comparison and analysis of genomes from different species to gain a better understanding of the genomic organisation and conservation and evolution of gene and genomic functions that would have contributed to speciation, adaptation and evolution and to similarity and differences across species (Meadows and Lindblad-Toh, 2017). The advances in genomics technologies, especially the proliferation of low-cost NGS platforms (Levy and Myers, 2016) have led to an abundance of high-quality sequence data that have enhanced the identification of

Fig. 1 High-throughput omics technologies provide large scale mapping of heterogenous molecular-level data. Computational methods for integrative multi-omics data analyses aim to uncover relationships across different cellular organisation layers represented by different omics datatypes to hypothesise the pathways and mechanisms underlying complex biological processes, which can then be leveraged to pinpoint biologically and therapeutically relevant genes and proteins (such as potential drug targets).

a large number of sequence and structural variants and are rapidly redefining the understanding of genotype-phenotype relationships (Shameer *et al.*, 2016).

Although genomics sequences have provided unprecedented insights into the gene function and evolution, they do not provide the context of these functional aspects such as spatio-temporal expression of different genes and changes in gene expression in response to different biological cues. To address these questions, genomics revolution was thus, soon followed by an increasing number of high-throughput studies that started mapping genome-wide gene expression profiles in specific cells and tissues in different biological contexts.

Transcriptomics

The genetic blueprint of an organism is encoded within its genome, but is expressed via transcription i.e., copying of the information from DNA into RNA that forms the key intermediate between the DNA and the protein. The sum total of RNA transcript population of a cell is known as Transcriptome and the study of transcriptome is known as *transcriptomics*. The two major and most widely used technologies for transcriptomics analysis are microarray and RNA-seq (Lowe *et al.*, 2017). Microarrays determine the abundance of mRNAs from a given sample, cell or a tissue via their hybridisation to an array of oligonucleotide DNA sequences or ‘probes’ that are immobilised on a solid surface (Lowe *et al.*, 2017; Schulze and Downward, 2001; Slonim and Yanai, 2009). DNA microarrays have emerged as a powerful medium for genomic and biomedical research to investigate the gene expression states underlying different physiological processes, for the characterisation of gene function and biomarker identification (Trevino *et al.*, 2007) and also for whole genome comparisons to investigate genomic variations (Gresham *et al.*, 2008). Another widely used technology to quantify the transcriptome is RNA-Seq that combines the usage of NGS with computational analytical tools to determine the presence and abundance of transcripts within a biological sample (Lowe *et al.*, 2017). Lately, RNA-Seq has emerged as the method of choice for large scale transcriptome mapping and for the identification of allele-specific expression, gene fusions and detecting alternatively spliced variants and non-coding RNAs even at the single-cell level (Hrdlickova *et al.*, 2017; Spies and Ciaudo, 2015).

With the rapid advances in transcriptomics technologies, there have been proliferating attempts at surveying the gene expression landscape across multiple tissues, cells and physiological processes such as mapping of genetic variation and its impact on the gene expression landscape in different tissues by the Genotype-Tissue Expression (GTEx) project (Consortium, 2013) and the Functional annotation of the mammalian genome (FANTOM) project (Consortium *et al.*, 2014). The availability of huge amounts of gene expression profiles from diverse physiological states have permitted the researchers to construct gene co-expression networks to assign functional annotations to different genes and to prioritise candidates for biological and clinical research (van Dam *et al.*, 2017).

Transcriptomics technologies measure the changes in the abundance of mRNA. However, most of the cellular functions are typically regulated at the level of proteins and thus, transcriptomic analyses often provides only an indirect measure of the cellular physiology. This limitation in turn has led to the development of high-throughput methodologies to simultaneously measure and understand the activities of a large number of proteins within a cell or an organism.

Proteomics

Proteins are responsible for a multitude of tasks within the cell. PPIs, for instance, are central to the organisation of macromolecular complexes and many enzymatic reactions that underlie nearly every cellular process. The goal of *proteomics* is to understand how the entire protein population of a cell or organism, i.e., the proteome, their dynamics and their interactions together contributes to and regulates different biological processes, including disease phenotypes. Proteomics can be used to identify and quantify cellular protein levels, characterise PPIs to generate proteome-scale PPI Network (PPIN) maps or to profile post-translational modifications (PTMs) within the cells. Proteomics approaches have, thus, emerged as effective tools in studies involving the investigation of biomedical, nutritional sciences, pathogenic infection, host-pathogen interactions, and molecular biology (Jean Beltran *et al.*, 2017; Moore and Weeks, 2011; Lum and Cristea, 2016).

With rapid advances in analytical capabilities, proteomics is being increasingly used to identify the components of biological systems (Sabido *et al.*, 2012; Aebersold and Mann, 2016). For instance, yeast two-hybrid system (Y2H), where the proteins of interest are fused to the fragmented TF domains and their interaction reconstitutes the functional TF and can be assayed by the downstream expression of a reporter gene (Fields and Song, 1989), is one of the most widely used techniques to detect binary PPIs on a proteome-wide scale. Another versatile experimental technology for proteomics is mass spectrometry (MS), which can detect variable proteins with higher sensitivity and measure the values in higher quantification. Studying temporal proteome alterations has become a popular approach due to the availability of well-established protocols and modern MS instrumentation. The accumulated proteomics data have enabled the researchers to carefully examine the temporally and spatially distinct phases of dynamic cellular processes. However, the data obtained from MS studies are typically huge. A typical cell reportedly contains over 20,000 different proteins, isoforms, and post-translational modifications. To extract useful information from this array of data, powerful protein quantification approaches have emerged, which are collectively classified as *targeted proteomics*; *targeted proteomics* approaches are becoming increasingly popular to address wide-ranging questions in many different systems biology and clinical studies (Ebhardt *et al.*, 2015). As the instrumentation has improved, the new bioinformatics tools to analyse the big data of proteome have also been developed (Calderon-Gonzalez *et al.*, 2016). Integrated MS approaches, antibody-based affinity purification of protein complexes and cross-linking and protein array techniques have contributed towards elucidating complex networks of virus-host protein associations during infection for a wide range of RNA and DNA viruses (Lum and Cristea, 2016). The labelling method is also one of the most useful methods to quantify protein levels, through the use of stable isotope amino acid labelled with C_{13} , H_2 , or N_{16} (Bantscheff *et al.*, 2012). These methods have immensely contributed to important biological discoveries and to the design of new therapeutics.

Metabolomics

Metabolomics is the newest of the 'omics' sciences. The metabolome refers to the sum total of low molecular weight compounds or metabolites such as amino acids, sugars, lipids etc. within a biological system (Krumsiek *et al.*, 2016). Metabolic compounds are typically substrates and by-products of biological processes and enzymatic reactions; they are widely involved in feedback regulatory processes in the cell and being the downstream products often directly influence the cellular or organismal phenotype and thus, metabolome is often regarded as the link between genotype and phenotype (Krumsiek *et al.*, 2016). Metabolomics aims to characterise the type and abundance of metabolites within a biological system at a specified time and under specific environmental conditions, thereby helping gain an understanding of varied metabolic processes (van Rijswijk *et al.*, 2017) and how their dysregulation may be correlated with the onset and progression of diseases (Tolstikov, 2016). *Metabolomics* is being increasingly used to investigate and understand diverse traits such as genetic variation and their correlation with metabolite concentrations (Suhre *et al.*, 2011; Kastenmuller *et al.*, 2015), gene expression patterns (Cavill *et al.*, 2016), biomarker and drug discovery (Wishart, 2016) and assessment of drug safety and efficacy (Ramirez *et al.*, 2013) and even personalised medicine (Tolstikov, 2016; Wishart, 2016).

As with proteomics, rapid strides in MS technologies have facilitated the detection and characterisation of a wide range of metabolites from various biological and clinical samples (Krumsiek *et al.*, 2016; Tolstikov, 2016; Wang *et al.*, 2015; Zampieri *et al.*, 2017) and also the development of new statistical and computational methods to store and analyse the huge amounts of emerging metabolomics data (Krumsiek *et al.*, 2016; Tolstikov, 2016; Xia *et al.*, 2015).

Integrative Analysis of High Throughput Omics Data

The availability of huge amounts of different types of omics data and their analyses have significantly contributed to advance our fundamental understanding of biological systems. However, the analyses of individual datasets offer limited and often disparate insights into the functions of different biological entities, with only a limited insight into how the different entities communicate with each other across different organisational layers. The first step towards an integrative multi-omics data analysis is the integration of different omics datatypes onto a single platform.

Integration of High-Throughput Data

Biological databases have emerged as invaluable resources for compiling, storing and distributing ever increasing amounts of omics data. To achieve multi-omics data analysis, the data from different omics databases must be linked together onto a single

platform. However, the heterogeneity and often inconsistencies of the data generated from the different high-throughput technologies and the formats used to store, manage and query them in different repositories makes the integration of multi-omics data and their analyses a non-trivial challenge. Despite the challenges, integrative data analyses promise holistic and more informative insights into disease biology and drug discovery (Ritchie *et al.*, 2015). Therefore, there have been innumerable efforts to develop new computational tools and approaches to integrate and analyse diverse biological data types that often differ in scope, design, content, analytical abilities as well as the targeted research audience (Chen *et al.*, 2011, 2016; Ge *et al.*, 2003; Gerstein *et al.*, 2002; Smith *et al.*, 2012; Huang *et al.*, 2009; Stein, 2003; Triplet and Butler, 2014).

Typically, the integration of different biological datatypes involves first identifying common elements among them that can be used to build relationships between the different types of biological entities. Among the many different frameworks for integrating and storing biological data, are the data warehouses that compile different biological datatypes onto a common platform, facilitate a wide range of queries linking different datatypes and different functional attributes and can produce a unified output for the user (Stein, 2003; Triplet and Butler, 2014). For instance, TargetMine is an integrative data analysis platform based on the Intermine framework (Smith *et al.*, 2012) that features different omics data types and analytical functions for gene set analysis and biological knowledge discovery (Chen *et al.*, 2011, 2016).

However, most integrated databases are equipped with limited data analyses capabilities and therefore there have been many attempts to develop more sophisticated standalone tools for integrative multi-omics data analyses that can be combined into an overall pipeline to link data generation to storage, analysis and prioritisation of biologically and therapeutically relevant candidates such as genes, transcripts, proteins and metabolites.

Analysis of Integrated Omics Data

A wide range of computational approaches have been developed for integrative analysis of multi-omics data to reduce the dimensionality of the large omics data sets, to identify biologically meaningful patterns and to prioritise candidate gene, proteins and biomolecules of interest (Ritchie *et al.*, 2015; Huang *et al.*, 2017). Broadly, such methods fall into unsupervised approaches such as clustering (Ronan *et al.*, 2016) and matrix factorisation (Li *et al.*, 2012) and supervised integrative analysis methods such as those based on network-based modelling (Robinson and Nielsen, 2016) or machine learning based algorithms (Lin and Lane, 2017). We discuss some of these approaches below.

Unsupervised Integration and Analysis of Omics Data

Unsupervised methods for data integration do not require a training dataset, rather they aim to analyse the data to uncover hidden patterns and/or underlying data structures and to gain and understand the relationships between different biological entities (Ritchie *et al.*, 2015; Huang *et al.*, 2017; Ronan *et al.*, 2016; Kirk *et al.*, 2012; Lock and Dunson, 2013). Clustering is one of the most widely used unsupervised methods for exploring patterns in large omics datasets and to identify subsets of correlated biological entities such as co-expressed or co-functional genes that are relevant to specific disease and cellular processes (Ronan *et al.*, 2016). Clustering approaches for integrative omics data analysis typically fall in the category of joint clustering approaches that leverage shared data features and relationships across diverse biological datatypes to analyse multi-dimensional biological data. As an example, the iCluster method simultaneously performs data integration and dimensionality reduction via a joint latent variable to capture biologically and clinically relevant sub-clusters (Shen *et al.*, 2012).

However, methods that exploit shared data structures to integrate and correlate biological data types may often overlook patterns and features that are unique to individual datatypes. This problem has led to the development of methods that are based on the Bayesian approaches to integrative omics data analysis that simultaneously take into account correlations across different datasets and datatypes as well as source-specific features for integrative clustering of biological datatypes (Kirk *et al.*, 2012; Lock and Dunson, 2013; Ray *et al.*, 2014).

Network-Based Models of Integrative Omics Data Analysis

Network models form an important component of supervised integrative biological data analysis. A network consists of *nodes* that represent different biological entities (gene, RNA molecules, proteins, metabolites etc.) that are connected with each other via *edges* that represent the biological connectivities (physical and/or genetic) between the individual entities, the edges can include PPIs, TF-TG interactions, MTIs and PCIs among others. Typically, network models lie at the heart of the systems biology approaches since they closely reflect genetic, physical and chemical relationships that exists between biological entities within and across different cellular organisations layers. Consequently, a wide range of network-based approaches and tools have been developed to collate and analyse large amounts of biological data to obtain a deeper understanding of cellular physiology and pathogenesis of various diseases (Yan *et al.*, 2017; Ritchie *et al.*, 2015; Huang *et al.*, 2017; Robinson and Nielsen, 2016).

Conclusions

The rapid strides in experimental technologies that can map and quantify the different organisational layers of the living system have contributed to the rapidly increasing scale and sensitivity of omics data. A better understanding of the living systems can only

come from a combined approach that seeks to integrate and analyse the different omics datatypes to unravel the complex networks that link different cellular organisational layers and drive the functioning of the cellular machinery. Consequently a large number of computational tools and pipelines using both supervised and unsupervised approaches have been developed for integrative analysis of multi-dimensional omics data.

However, several challenges persist in extracting biologically meaningful information from the analysis of multi-omics data.. For instance, the experimental platforms used to generate omics data and biological databases that are used to annotate them are far from comprehensive in their coverage of the biological systems. Additionally, the protocols for sample preparation, performing omics experiments and processing the raw omics data and their normalisation can vary substantially among researchers, which may often lead to difficulties with data sharing, analysis and reproducibility. Nevertheless, further advances in the field will facilitate more holistic approaches that can be applied to obtain deeper insights into the dynamics of complex relationships across multiple cellular organisational layers to gain more knowledge of the mechanisms underlying key biological processes including onset and pathogenesis of diseases.

Introduction

Gut profiling is the study of unique microbial fingerprints found inside the human gut with the objective of understanding their associations with well-being and disorder. There seems to be a never ending debate on the actual number of microorganisms in the human body, specifically in the gastrointestinal (GI) tract (Sender *et al.*, 2016). The latter accounts for more than a thousand (~1000–1150) different bacterial species (Sánchez *et al.*, 2017; Qin *et al.*, 2010) with Firmicutes, Bacteroidetes, Actinobacteria, and Proteobacteria as common occurring phyla (Arumugam *et al.*, 2011). It is believed that there are around 3.3 million unique genes in human gut which is 150 times more than the genes in human genome (Zhu *et al.*, 2010a, b). Researchers are intrigued to know that no two individuals have exactly the same composition of bacterial species in their guts just as the fingerprints. The gut microflora have a vital role to play in wide variety of metabolic, trophic and protective functions which includes: (i) Facilitating withdrawal of energy from non digestible polysaccharides producing short chain fatty acid (SCFAs), vitamins and antioxidants (ii) detoxification of the deleterious xenobiotics (iii) modulation and development of immune-system (iv) Epithelial cell growth and differentiation (v) secretion of anti-microbial products, providing the barrier effect against the pathogenic bacteria through the development of colonization resistance (vi) nerve regulation, controlling mood and behavior (Guarner and Malagelada, 2003; Ly *et al.*, 2011; Sun and Chang, 2014; Vernocchi *et al.*, 2016; Mayer *et al.*, 2014).

Microbiome research suggest that dysbiotic shifts i.e., the changes in the make-up of gut microbiota in terms of number or categorization may imbalance the homeostatic harmony causing conditions such as obesity (Ly *et al.*, 2011; Alard *et al.*, 2016), inflammatory bowel diseases (IBD) (Knights *et al.*, 2013; Ferreira *et al.*, 2014; Norman *et al.*, 2015), allergy and asthma (Abrahamsson *et al.*, 2014; Ly *et al.*, 2011), chronic brain diseases (Mayer *et al.*, 2014), colorectal cancer (Sobhani *et al.*, 2011), type II diabetes (Qin *et al.*, 2012; Karlsson *et al.*, 2013; Moreno-Indias *et al.*, 2014; Musso *et al.*, 2010), rheumatoid arthritis (Scher and Abramson, 2011), fatty liver disease (Miele *et al.*, 2009), lesional skin (Ganju *et al.*, 2016) and numerous other diseases (Fig. 1). Thus, to understand the basis of dysbiotic shifts, it is important to first discover and characterize these communities by answering the following key questions: (1) Who is there in the gut? (2) What roles are they playing? (3) How they affect the gut functionally? (4) How their abundance changes with disease conditions? Because of the scale, complexity and the impact gut microbes has on an individual, the ecosystem of the colon has been the most diligently studied body habitat (Lloyd-Price *et al.*, 2016).

Background

The time since the microscopic organisms have been discovered during 1665–1683 by Robert Hooke and Antoni Van Leeuwenhoek (Gest, 2004), mankind has travelled for more than 300 years to understand the integral relationship of them with us. There is a deep-seated alliance of human beings with the cohort of microorganisms, often called the microbiome (Lederberg, 2000), and hence it will be not be an exaggeration to call the microbiome as the “second genome” (Grice and Segre, 2012; Zhu *et al.*, 2010a,b). While human beings share 99.9% similarity with each other at the genome level, our gut microbes can be very

Fig. 1 The ecosystem of gut microbiome. At the centre lies the core gut microbiota. The inner small circles represent the factors that affect the composition and diversity of the gut microbes. The figures projecting out from the outer circle represent the diverse class of body organs affected by the gut microbiome interactions with human host.

much different providing us different phenotypes. The gastrointestinal tract which is sterile at birth (Ly *et al.*, 2011) starts the very first colonization right after the birth and in the following few days after delivery. Studies have shown that this colonization is largely dependent on the way of delivery (natural or c-section) and the kind of food provided in infancy (mother's milk or formula) and adulthood (vegetarian or non-vegetarian) (Jandhyala *et al.*, 2015).

A number of large scale collaborative projects have been initiated reinforcing our understanding of functional prospective of microbiota on human health. It includes "Metagenome Human Intestinal Tract project" (MetaHit project: see "Relevant Websites section") initiated in year 2010 having considered 124 European adults stool samples most of which were healthy individuals. This project was funded by the European Seventh Framework Program until 2012. Its objective was to understand the link between the human intestinal microbiota and two disorders of increasing incidence in Europe namely inflammatory bowel disease and obesity. Later in 2012, the "Human Microbiome Project" (HMP: see "Relevant Websites section") was launched to define microbes existing in 5 major body sites of 242 healthy adult from United States using 16S and shotgun metagenome approach. By end of 2013, the study of European population has begun under MyNewGut project (see "Relevant Websites section") with an aim to identify specific dietary strategies to improve the long-term health of the population. One more project entitled "American Gut Project" was conceived in 2012 which is the world's largest crowd-funded citizen science project. The participants of this project are American citizens who learn about their own microbiome and also contribute for samples and money required for executing the project smoothly.

Although there are number of molecular techniques ranging from culturing to fingerprinting, DNA microarray and clone sequencing which have been used since last many years, Next Generation Sequencing (NGS) has given a new insight into study of gut microbes. Several sequencing approaches have been deployed so far including shotgun metagenomics, microbial transcriptomics, whole genome microbial sequencing and marker gene sequencing. Additionally, NGS has also lead to the generation of giga bytes or even terabytes of data. Hence, it becomes essential to process, manipulate, analyze, visualize and store the sequencing data in a

structured and meaningful manner. It is at this point where bioinformatics approaches are playing a pivotal role and various scientific methods, tools and protocols have been formulated to study the microbiome and achieve the desired outputs.

Approaches for Gut Microbiome Study

Molecular Techniques From Pre-ngs to NGS

Before the advent of NGS technologies, early researchers have employed a number of techniques which can be broadly divided into two categories (Rastogi and Sani, 2011) as given in Fig. 2:

1. Culture dependent,
2. Culture-independent.

Culture dependent

The basis of culture dependent methods is isolation of microbes followed by inferring their composition on standard commercial growth media under controlled laboratory conditions (Handelsman, 2004; Kirk *et al.*, 2004). To maximize the cultivable fraction of microbial communities, many improvements have been made in cultivation method and culture media so far to mimic the natural environments (Rastogi and Sani, 2011). This methodology remained as golden standard for many years for characterization of microbes (Fraher *et al.*, 2012). However, culture dependent approach is not preferred for gut microbiota study as this ecosystem is considered as most diverse and it contains large number of unculturable bacteria (70%–80%) (Eckburg *et al.*, 2005;

Fig. 2 Approaches for gut microbiome study. Pictorial representation of the different approaches (partial/whole community analysis) to study gut microbiome. Apart from DNA samples (metagenomics), RNA (metatranscriptomics study), protein (metaproteomics study) and metabolite (metabolomics study) samples are often useful to get a complete picture of the gut microbial interactions. Note: Modified from Rousseau, C., Butel, M.J., 2015. High-throughput techniques for studying of gut microbiota. *Advances in Probiotic Technology* 146.

Hayashi *et al.*, 2002; Suau *et al.*, 1999). Due to this shortcoming there was paradigm shift from culture dependent to culture independent methods.

Culture independent

The basis of culture-independent method is isolation of nucleic acid to analyze selected marker genes such as 16S rRNA or any other functional genes (for example, gyrase beta subunit or recombinase (A) to characterize prokaryotes community. In general, this molecular technique can be divided into (1) partial community analysis approaches (fingerprinting, clone library method DNA microarray, qPCR) (2) whole community analysis approaches (whole genome sequencing, metagenomics, metatranscriptomics, metaproteomics and metabolomics) depending upon the strength of techniques to exhibit the microbial diversity and their function (Rastogi and Sani, 2011).

Partial community analysis approaches

(a) Fingerprinting techniques:

Fingerprinting techniques namely denaturing or temperature gradient gel electrophoresis (DGGE/TTGE), terminal restriction fragment length polymorphism (T-RFLP), automated rRNA intergenic Spacer Analysis (ARISA), Amplified ribosomal DNA restriction analysis (ARDRA) and single-strand conformation polymorphism (SSCP) are commonly implemented to study complex microbial ecosystem like GI (Zoetendal *et al.*, 2004). These are cheap and rapid methods and thus are preferred even today when large number of samples are involved and aim of the study is just to identify dominant bacterial group (more than 1%) (Hamady and Knight, 2009). Studies implementing these techniques have revealed that species richness increases along the length of the gut (Rousseau and Butel, 2015). However, the main drawback of these techniques is that data from different studies cannot be combined and thus compared.

(b) Diversity microarrays:

Diversity microarray is one of the promising techniques to study gut microbes (Zoetendal *et al.*, 2004). It works on the principle of hybridization of probes (representing known genes attached to the glass surface) with DNA or RNA present in sample detected by means of fluorescence. HuGChip and PhyloChip are commonly used microarrays for microbiome studies (Tottey *et al.*, 2013; Palmer *et al.*, 2007). In 2003, for the first time (Call *et al.*, 2003) scrutinized the antibiotic resistance genes in intestinal microbiota using microarray. IBD, a disorder of gut microbiota was also studied in Kang *et al.* (2010). using phylogenetic microarray. Main shortcoming of this technique is that the sequences to be used in probe designing have to be known, though if not at specific level but at upper level (phylum or family). Thus, this technique cannot be used for undiscovered microbes (DeSantis *et al.*, 2007). However, its potential to process number of samples simultaneously makes it favorable method for many studies.

(c) Clone Library Method:

Here 16S rRNA gene is amplified from the samples and then cloned followed by its sequencing. 16S rRNA database for instance Ribosomal Database Project (RDP), Greengenes, GenBank are then used to identify microbes represented by cloned sequences (DeSantis *et al.*, 2007). Suau *et al.* were the first to characterize microbes in gut utilizing Sanger sequencing in the year 1999. Though, it is considered as “golden standard” for preliminary diversity study, the drawback of using this technique is that it requires large number of clones to be prepared and sequenced even to capture half of the diversity of sample making it labor-intensive and expensive technique (Rousseau and Butel, 2015).

Whole community analysis approaches
